An Address
ON
CHILDREN IN GENERAL PRACTICE:
A STUDY BOTH OF TEMPERAMENT AND OF DISEASE.

Being the Lloyd Roberts Memorial Lecture delivered at St. Mary's Hospital, Manchester.

BY HECTOR CHARLES CAMERON,
M.D. CAMB., F.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE DEPARTMENT FOR DISEASES OF CHILDREN, GUY'S HOSPITAL.

I AM told on all hands, by all who are concerned with the struggle to control him, parents and pedagogues, priests and physicians, that since the war the nervous child, so called, has become increasingly common. We know him well—pale and thin, wasting his meagre little body by the intense energy which he throws into the whole business of living, subject at times to fits of strange irritability or to uncontrollable outbursts of temper, a bad sleeper, a great refuser of food, never still for a moment, often squinting, stammering or incontinent of urine, prone to attacks of vomiting heralded perhaps by yawning, prostration, lassitude, foul-smelling breath, furring of the tongue, and a persistent irregularity of temperature which arouses fears of some latent tuberculous infection. At his best he shows a certain fragility of aspect which is a constant source of anxiety to his parents; at his worst, in response to the various stresses of his little life, to undue excitement, to some unusual exertion, or to some trivial and passing infection, the deterioration in his physical powers, in his mental achievements, and in his moral control may afford real and reasonable cause for alarm.

The study of such a child may be approached from many points of view. We may regard him as presenting in the main a problem in management. How sensitive he is to the influence of his surroundings at home or at school! Or we may concentrate attention upon the body rather than upon the mind, upon those defects of posture and of muscular coördination and control which are in a sense the outward and visible signs of nervous irritability and fatigue. Or, again, we may view him from the standpoint of the biochemist and stress the ætiological importance of that peculiar and characteristic instability of metabolism which he inherits from a stock, intellectually gifted perhaps, but often nervously unstable and prone to suffer from a variety of disorders such as gout, eczema, asthma, or migraine, all of which are expressions of some inborn tendency to errors of metabolism. Mind, body, and the metabolic processes of the body—let us glance at each in turn.

MIND AND MANAGEMENT.

We may perhaps define the nervous child as the child who is most sensitive to the influences of the grown-up persons who are in charge of him and who care for him. What is said of him, thought of him, feared for him, that he tends to become. In good hands, when his parents are sensible, self-confident, and care-free persons, who take delight in his achievements and are in no way unduly perturbed by infantile delinquencies or trivial disturbances of conduct or of health, his progress may be more rapid than is the rule. Upon this element of suggestibility and of sensitiveness to the personal influence of others the whole of education reposes, and the type of child whom we are considering is capable of very rapid movement in either direction forwards or backwards. But to any mistake of management he responds with a maximal disturbance. All children, and nervous children more than most, at some time or other may sleep badly, or refuse food, or wet the bed, or be obsessed by some particular fear; but those troubles are transitory and trivial or grow to the proportions of formidable misfortunes according as they are cut short, because they are dealt with lightly and with optimism, or are perpetuated, because they are kept in the forefront of the child's consciousness by the too obvious concern and apprehension of the parents.

Again, a great deal of infantile misconduct is clearly designed by the child or forced upon the child by his desire to produce the maximal emotional response in his mother. No one can be successful in the management of little children who has not acquired the art of hiding from them their power to disturb. Those of us who have crying children, for example, are generally persons who are immeasurably distressed by the cry. A fixed determination to oppose and to make strain in the opposite direction is characteristic of many dominating, egotistical, nervous children. This negativistic attitude in the child is fostered by a common fault of management, a management which while powerless to control, yet never ceases from attempts to control. On the one side is ranged the child's strong, irritable, and restless determination to oppose; on the other, is arrayed a pitiful armament of never-ending reproofs, expostulations, appeals, threats, and trivial unheeded punishments.

Punishment no doubt can be made effective, but in general it is true that it is precisely the parents who suffer in this way, the parents whose distress and preoccupation with the trouble have been the cause of the whole difficulty, who are least able to administer punishment sufficiently severe to bring the child to silent acquiescence. Punishment which leaves the child still dominating the position by his cry, still established in his determination not to yield, is worse than useless because it aggravates and does not control the situation.

This spirit of negativism, this restless resistance against all traction that is exercised in too obvious and in too peremptory a way, is apt to find expression in all the activities of a little child's life. It is a main cause of refusal of sleep, of refusal of food, and of refusal to get the bowels open, and of all the ills that follow therefrom.

Thus that veritable anorexia nervosa, which so often afflicts the only child of well-to-do parents, finds much of its explanation in this negativism. Coaxed, urged, entreated, forced to eat, day in and day out, the mere sight or sound of the preparation of food may provoke a paroxysm of resistance. Yet such a child will often descend from his chair, in which the struggle has been waged, and astonish his parents by scavenging greedily for crumbs upon the floor. A small boy, who resolutely and successfully refused all food at meal times, was described to me as being kept alive by a propensity from which the united efforts of his mother and nurse could not break him, for devouring the crusts from a paper bag, armed with which he was sent to feed the ducks in the park. His tearful mother had even got into the way of inserting some nutritious pieces of brown bread and butter into the parcel in the sure hope of their consumption by the child. In such a case an alteration in the management may achieve the happiest results. The mother must hide from the child her ardent desire that he should eat. Food must be doled out with apparent reluctance. The child must be made to feel that the one thing on which his parents feels strongly is that he must not have too much. It is not a question of deceiving the child. The trouble has originated in, and been kept up by, the too obvious disappointment and too insistent entreaty of the mother. She must correct and it may be, for the time being, over-correct her own attitude in order to restore the sensitive child's position to the normal.

ENURESIS.

Let us for a moment examine the genesis and significance of another common symptom of the hypersensitive and nervous child—enuresis. I see no reason why we should not recognise this common incontinence of urine, by night or sometimes by day,

665272

as hysterical. From one point of view it is, of course, true to say that all children or most children are physiologically hysterical if by that we mean no more than that the most normal child is prone to fall under the influence of any suggestion which is persistently made to it by the grown-up people upon whom it relies for support and protection. In about 6 per cent. of my cases of enuresis the suggestion has spread in the anxious mind of the child from the urethral to the rectal sphincter and incontinence of fæces has been added to incontinence of urine. In such cases the condition, although purely functional, resembles very closely the incontinence of fæces which results from some transverse lesion of the spinal cord. The sphincter ani is palpably toneless and the anus patulous. Nor does the child feel the finger inserted in rectal examination. We have here, undoubtedly, I think, an hysterical paresis of sphincter and an hysterical anæsthesia of the rectum. I think it possible that a similar hysterical paresis and anæsthesia exists at the neck of the bladder.

In general, it is clear that the child with enuresis is a hypersensitive child to whom his infirmity is absolutely abhorrent. It may hang like a cloud over his whole life. He is incontinent not because he does not care, but because he cares too much. Doubtless backward children and children of low mentality generally are difficult to train to habits of cleanliness, but their failure in this respect is then in keeping with and does not contrast with the general level of their intelligence and achievement. In enuresis the general level of the child is often high. His æsthetic sense is, as it were, too highly developed. The accident distresses him unduly. He cannot drive it from his thoughts. He fears and dismally anticipates its recurrence. No doubt many children compensate by assuming an attitude of ostentatious unconcern, which may deceive those who do not know the child or who have little understanding of children. No doubt, too, there are times and seasons when the child forgets his trouble. Just so in dyspareunia in early married life, existence is not always or wholly overclouded and some genuine happiness may be found in the ordinary activities of life. Yet the thought of the trouble is always in the background, only to be entertained to become overmastering. And far back in the infancy of this sensitive, suggestible child, paling, flushing, perhaps, too, stammering, who shows himself, however careless and insensitive to all appearance in this one respect, in all other respects easily upset by reproof, unable to stand up against criticism, and greatly upset by any situation in which he finds himself conspicuous or ridiculous, or in which he feels he has done the wrong thing, far back in his infancy, I say, is the shocked, grieved face of the mother or nurse uttering words of reproof or expressing disgust at his infantile defilement. With the majority of children such methods are commonly successful. But with the child so predisposed, the management that lays too great stress upon the occasional accident and too little upon the growing control, leads directly to the development of the disorder which we call enuresis and which may persist, greatly to the detriment of the child's whole life and development, until the growth of personality and self-confidence ultimately brings freedom from the grip of childish fears and obsessions.

It is a disorder very difficult to treat, but perhaps less difficult to prevent. Among the children of the well-to-do threats and punishments are not commonly resorted to. Yet the boy is well aware of the anxiety of his parents and their preoccupation with his trouble. The mother of the boy with enuresis is almost always profoundly agitated and profoundly pessimistic. Everything has been tried, nothing avails. To effect a cure we must succeed in ousting this pessimism from the home and substituting for it an all-embracing optimism. The child will readily grasp at any hope of cure. I have seen one boy cured by a vegetarian diet, another by denying him all vegetables. Within the boy's mind the hope of cure is often strong, the mother too often is most hopeless. Yet it is to the mother that he turns for relief from overmastering oppression.

I have chosen refusal of food and enuresis as examples in different types of child, the one often dominating and egotistical, the other often introspective and lacking in self-confidence of the reaction to specific faults of management.

The Metabolism of the Nervous Child.

Of the biochemistry of emotional states we know very little. Nevertheless, I am so impressed with its importance that I propose briefly to examine our present knowledge especially with regard to the metabolism of fat in the nervous child. It is characteristic of many of these children that they tend, as it were, to live upon a curve or in a cycle, with an inveterate tendency to fall suddenly, and often without ascertainable cause, from a state of good health and well-being to a state of indefinite illness in which complaints of prostration and fatigue, pallor, indefinite transitory pains in all situations, persistent irregularity of temperature, yawning, sweet smelling breath, irritability of temper, vomiting, and loss of weight are more or less constant. We hear much from the parents of these bouts, or turns, or attacks. In many of them, but by no means in all, gastro-intestinal symptoms dominate the picture, sometimes attacks of mucous diarrhœa, more often insistent distressing vomiting. In the worst and most typical cases we encounter the classical picture of the so-called periodic or cyclical vomiting. A considerable experience of this type of child has seemed to me to indicate the essential identity of all these attacks, whether mild or severe, whether always culminating in violent vomiting or whether vomiting is occasional or even absent.

The energy expended upon emotional activity and upon muscular activity is alike derived from the stores of carbohydrate in our bodies. The carbohydrate is, as it were, the petrol of choice. But we have little reserve of carbohydrate stored in our bodies. An adult man may possibly have some 8 ounces in the form of glycogen, distributed equally between the liver and the muscles. The carbohydrate reserves are replenished by every meal with its carbohydrate content, they are diminished in the interval between meals and especially in the long interval of the night, and they are quickly depleted by exertion, by great emotional excitement, and by starvation, whether by abstinence from food or as a result of vomiting, as well as by pyrexial states generally. In the absence of sufficient carbohydrate the individual is forced to fall back upon a different petrol and to consume the body fat which is the main storehouse of energy. Now the metabolism of fat is only successfully completed in the presence of and with the help of a sufficient amount of carbohydrate. If the body is short of carbohydrate, the fats are not completely metabolised to water and oxygen and there then circulate in the blood certain products of the incomplete combustion of fats, the so-called ketone bodies, especially acetone and diacetic acid, which are excreted for the most part in the breath but which also, in severe cases, appear in large amounts in the urine.

It is characteristic of the type of child whom we are now considering that all the ordinary stresses of his life, emotional excitement—a new school, for example, or a change of master—undue exertion, as from a long day's sight-seeing or a train journey, starvation, even the physiological starvation of the night, or a mild and trivial infection, produce with unusual readiness this state of ketonæmia and a disturbance of the acid-base-balance. The nervous child has in general a high basal metabolism. The fires of his being burn very brightly. His need for carbohydrate is probably high. At the same time there is some evidence that his powers of metabolising fat are relatively low. On a diet rich in fat and with little sugar and starch, with much cream, milk, butter, and eggs, his troubles grow apace.

During the recurrent bouts of illness the consumption of body fat as shown by the great loss of weight is often distressingly great. It is probable that the failure to utilise fats successfully and without the production of symptoms is dependent upon the depletion of the carbohydrate reserves or upon an inability to mobilise such carbohydrate as is available. Ketonæmia, a corresponding diminution in the alkaline reserve of the blood, and a slight and transient fall in the percentage of sugar in the blood are constant findings in the more severe cases. The point which seems to me to be of importance is to realise that while all children, just because they are children, are prone to develop ketonæmia, the nervous child has this tendency in an especial degree.

The nervous child has in this sense an unstable metabolism, and it is equally true that when the metabolic disturbance has arisen the nervous symptoms from which he tends to suffer always become aggravated. Thus during these bouts of ketonæmia we commonly find exacerbations of such symptoms as night terrors, enuresis, masturbation, or stammering. In night terrors the confused struggling of the frightened child, with pale face and wide open eyes, oblivious for long of the reassuring presence of the mother, recalls the similar state produced by very light chloroform anæsthesia, also a ketonæmia. Night terrors are, I think, very frequently best controlled by the free administration of glucose at bedtime. Similarly the profound torpid sleep of many children with enuresis may be symptomatic of ketonæmia. But almost all nervous symptoms are at their height during the exhaustion, irritability, and state of anxiety or apprehension which is characteristic of the bout or attack. We may perhaps compare the unhappy condition of these children with the similar state of nervous unrest and anxiety which follows directly upon the hypoglycæmia produced by an overdose of insulin, and which is then controlled, almost as it were by magic, by the provision of a few lumps of sugar.

The Physical Aspect of the Nervous Child.

In pronounced states of ketonæmia we encounter certain alterations in the physical state and aspect of the child. To those who are familiar with the distressing condition which we call cyclical vomiting the appearance of a child so affected is characteristic. We are struck at once by the pallor of the face, contrasting with the red and dry lips, by the great muscular relaxation, and by the utter prostration. Sometimes there is great restlessness and excitement, sometimes profound somnolence, almost coma. The pulse is rapid, the blood pressure is low. Especially the differential pulse is high. The respiration is often ample and deep, yawning is frequent, and the breath apt to be charged with acetone. The bowels are usually constipated, although sometimes there is diarrhœa with much mucus in the discharges. The tongue is furred, often there is painful ulceration of mouth or lips. The temperature curve is usually irregularly raised, although characteristically the skin may be moist and cool and there may be no other signs of fever. Thus it usually happens that the height of the pyrexia is, as it were, a surprise, accidentally revealed by the thermometer. Thirst may be great, but food is usually resolutely refused. Headache, giddiness, and nausea are common complaints. The vomiting may be so severe and persistent as to be by far the most prominent symptom, or it may be slight and occasional, sometimes even altogether absent.

The most constant and striking feature of such an attack is, I think, the extreme muscular relaxation which accompanies it and is caused by it. In a bad case the abdominal muscles are as toneless as in deep chloroform narcosis. Not long ago it happened that I was called with a surgical friend to see a little boy, who had long been subject to cyclical vomiting, and who, some days before, had had an operation for removal of tonsils and adenoids. As is not unusual in such cases the combination of the anæsthetic, the emotional disturbance produced by removal from home, and the relative starvation consequent upon the operation, had provoked a severe attack of ketonæmia. During recovery from the bout of vomiting he developed an intussusception. So toneless were the muscles of the abdominal wall that the surgeon had no difficulty at all in reducing the intussusception by manipulation through the abdominal parietes without laparotomy. The ketonæmia of chloroform could have produced no greater relaxation.

The tonelessness of the skeletal muscles and of the vasomotor muscles, perhaps, too, of the intestinal muscles, seems to me the most characteristic symptom of those recurrent metabolic crises which we know as "periodic" or cyclical vomiting. Although this amyotonia is greatly increased by and during an attack, it persists in great measure in the interval between the attacks. It gives to many of these nervous, eager, and excitable children a characteristic aspect and a characteristic posture which sometimes enables us to recognise them at a glance as subject to attacks or bouts of prostration with or without vomiting, such as I have described. Indeed, the symptoms of the exacerbation, though they are then of greater severity, are the same symptoms which are characteristic of the child between the attacks—amyotomia, pallor, proneness to fatigue, foul-smelling breath, yawning, persistent slight elevation of temperature, irregular action of the heart, and a failure to lay on any body fat.

Thus if we examine critically the body of one of these nervous children we cannot fail to observe that its general lines express exhaustion and fatigue. The posture is the reverse of the alert and well-braced stance inculcated on the drill ground. Under drill the soldier virtues are developed—resistance to fatigue, presence of mind, quickness to obey, precision of movement, and so forth. The lax and toneless stance of the nervous child is in keeping with his conspicuous deficiency in all those valuable qualities. His body is apt to be balanced, rather than held erect by muscular tone. Hence the curves of the spine are all exaggerated. A too great lordosis carries the shoulders far backwards and the abdomen into unpleasing prominence. A secondary compensatory curve in the cervical region becomes necessary in order to bring the eyes into line. The weight of the dependent arms pulls the shoulders forward and everts the scapular border. The somewhat flattened thorax is too soft and too compressible. Often it shows a significant depression of the lower end of the sternum, so that its outline on cross-section is kidney-shaped. The arch of the foot yields when the body-weight is put on it, while knees and elbows are capable of considerable hyperextension.

The pale face, with livid lines under the rather full underlid, from vasomotor paresis, adds to the woe-begone aspect. Although the child's interest in life, and his restless determination to oppose, may never seem to flag, and although every attempt to induce him to rest may be resented, yet his general aspect clearly indicates a state of fatigue.

Two further points only, of some clinical interest, need be mentioned. I cannot but be struck with the number of children, with symptoms such as these, who show some elevation or at least some instability of the temperature curve for weeks and even months at a time. The circumstance that this disturbance of fat metabolism is of itself sufficient to produce some degree of pyrexia in certain children does undoubtedly greatly add to our responsibilities and perplexities. It affords grounds very often for suspicions of latent glandular tuberculosis, or, because of the easily fatigued heart and the frequent presence of functional heart murmurs, of acute rheumatism with cardiac involvement. In my experience in a very large number of cases, this pyrexia, due not to infection but to some disturbance of metabolism, is at once controlled when sodium bicarbonate in doses of 100 to 200 g. daily is given. I have seen many cases in which this raised temperature, which had persisted

for months and given rise to alarming suspicions, has fallen straightway to the normal within 24 hours of the intake of sufficient alkali. But in the second place the matter is even more complicated by the frequency with which such a child does fall a prey to infection. Not only does the condition often develop as a result of some specific underlying infection, but it carries with it some lowering of the defences of the body against infection. It is clear that even in adults in states of great exhaustion from physical and emotional expenditure, immunity tends to fall. Cold-catching children seem to me to be divided into two groups: (1) those with visible and persistent infection of the lymphatic tissue in the nasopharynx, and (2) those pale and restless little creatures in whom the local reaction in the nasopharynx is often most trivial, but who respond to every trifling infection by a most unmistakable exacerbation of the metabolic disturbance to which they are prone. The metabolic component and the infective component of the whole are so intermingled as to make it often difficult to distinguish which is primary and which secondary.

The mind, the body, and the metabolic processes of the body, we cannot separate their study. Each merges into the other. One is tempted to add also the infective states of the body. In practice among children it is not the diversity of kinds of infection, so much as the diversity of the response of different children to the same infection, that makes the subject of such difficulty and of such interest. If a whole household falls a victim to some influenza or infective catarrh, while his brothers and sisters may respond by moderate and short lived pyrexia, clear evidence of local catarrhal reactions and a rapid convalescence, the child of the type we are now considering may appear to have been but very slightly infected, but there follows a prolonged deterioration of the general health such as I have described.

TREATMENT.

In the management of these difficult little people, wise, understanding, and considerate control is of supreme importance. Nor can we doubt the immense value of physical exercises, drill, dancing, and gymnastics. From the more medical point of view treatment may well concern itself with the attempt to control the tendency to the accompanying or underlying metabolic disturbance. In practice among the well-to-do we constantly find that the diet of these children contains a very large amount of fat. There is much propaganda in favour of fat. No doubt, as a whole, the children of the poor are fed upon a diet too largely carbohydrate. The number of calories of carbohydrate to be purchased for a penny is very much greater than the number of calories of fat. Under such circumstances the routine addition of milk to the diet may have the happiest results. But in the case of these particular children the boot is often on the other foot, and larger quantities of milk, butter, cream, and eggs are being given than can be metabolised successfully. Especially when the child has lost weight and has grown tired and thin in convalescence from a bout of acidosis, the parental agitation is apt to show itself in a heavy addition to the diet of cream, top milk, and cod-liver oil. Yet it is just at these times that the child is least able to deal with even moderate amounts of fat. At his best, when in free play in the open, when his body is whipped into a glow by exposure to sun and air, there may be no difficulty in dealing with the fat. When confined to the house, when convalescent from illness, when of necessity covered by impervious clothing, a diet rich in fat may well provoke or prolong the disturbance. And yet it is not the fat itself that has the deleterious effect. We must think in terms of the ratio of fat to carbohydrate in the diet, of the so-called ketogenic-antiketogenic ratio. For these children much carbohydrate is necessary to metabolise comparatively little fat. A free provision of carbohydrate is as necessary as a moderate limitation of the fat.

Formerly, I have no doubt wine was a very frequent and in some ways a valuable prescription. A bottle of port a day was adjudged necessary to combat the condition in the childhood of the younger Pitt. No doubt by means of alcohol, available carbohydrate is provided for the blood more rapidly than by any other means. I generally prescribe glucose in powder, about 2 ounces in the day between meals. The glucose appears to be absorbed quickly from the stomach, does not cause intestinal fermentation or diarrhœa, and seldom produces urticaria papulata. It is a most efficient means, given in these doses, of combating the tendency to ketonæmia which always seems present in these children. Disappointing results will, of course, be obtained in those cases in which the disturbance of metabolism is secondary to and symptomatic of some persistent and underlying infection — tuberculous glands, for example, or infected tonsils. Thus, in a child with ketonæmia and infected tonsils both components of the illness must be dealt with. The shock, the interference with the intake of food, and the anæsthetic of themselves tend to cause exacerbation of ketonæmia, and will sometimes make it appear as if the state of the child after an operation was much worse than before. Of the cold-catching children not helped by tonsillectomy, many belong to this group. Even when tonsillectomy is ultimately beneficial and much needed, there may be at first a great exacerbation of the symptoms of metabolic disturbance.

Glucose may even sometimes be a valuable help in the treatment of specific nervous disorders, masturbation, enureses, exhaustion, dyspepsia, or night terrors which seem to me often to accompany and to be increased by the underlying disturbance of the acid-base balance.

All are agreed on the advantages which sometimes follow the prescription of a small daily dose of alkali. Its power to control the common symptom of slight continued pyrexia I have already mentioned. The hypoglycæmia, the ketonæmia, and the diminution in the alkaline reserve, which would appear to be comparatively constant biochemical findings in these children, can sometimes be successfully combated by these simple measures, with consequent improvement in the mental and physical state of the child.

CARDIAC INFARCTION AND CORONARY THROMBOSIS.

BY JOHN PARKINSON, M.D., F.R.C.P. LOND.,
PHYSICIAN (WITH CHARGE OF OUT-PATIENTS) AND PHYSICIAN IN CHARGE OF THE CARDIOGRAPHIC DEPARTMENT, LONDON HOSPITAL; PHYSICIAN TO THE NATIONAL HOSPITAL FOR DISEASES OF THE HEART;
AND
D. EVAN BEDFORD, M.D., M.R.C.P. LOND.,
ASSISTANT PHYSICIAN TO THE MIDDLESEX HOSPITAL.*

WHEN a man of advancing years is seized while at rest with severe pain across the sternum which continues for hours and which is accompanied by shock, collapse, and dyspnœa, he has an anginal attack of no ordinary kind. It is only reasonable to suppose that something definite and material has happened in the heart, and investigation is actually proving that such attacks are the result of an acute infarction of the heart muscle from coronary occlusion.

Coronary thrombosis is a complication of arterial disease which is comparable with cerebral thrombosis, both pathologically and in its clinical manifestations. Until recent years it was regarded as a terminal complication of angina pectoris, an event of pathological interest in relation to sudden death. But now a clinical syndrome has been assembled so that to-day in most cases the diagnosis can easily be made during life. The clinical recognition of coronary thrombosis

* Working under the Paterson Bequest, Cardiographic Department, London Hospital.

is proving of great practical importance. In some cases the event may closely simulate acute abdominal conditions such as perforated ulcer, so that some have been surgically explored. In others an early diagnosis and prompt confinement to bed may mean the difference between life and death. Almost always the distinction from ordinary angina will modify the treatment and influence the prognosis. As many subjects of coronary thrombosis may recover from the attack as succumb to it, so that in future its diagnosis and course must take an important place in clinical medicine.

We happen to have had special opportunities in a general and special hospital, and in practice, of seeing many patients with these attacks and of watching their progress with special regard to the prognosis and the changes in the electrocardiogram which is often affected in a characteristic way. The present paper is based on the clinical study of 100 patients who had experienced one or more prolonged severe attacks of anginal pain, and in whom no diagnosis other than myocardial infarction seemed possible. Doubtful cases and those of post-mortem interest only have been excluded. We have made a supplementary study from the records of the Pathological Institute of the London Hospital from 1922 to 1926 for comparison; in these records clinical details were usually available. Altogether we have post-mortem records of 83 cases.

Historical.

The literature of the latter half of the nineteenth century contains numerous accounts of cases of fatal angina pectoris where coronary thrombosis was found post mortem, yet it was not until 1910 that any real attempt was made to establish cardiac infarction as a clinical entity. This is surprising in view of the fact that coronary thrombosis was correctly diagnosed during life by Hammer [9] as early as 1878.

The pathological aspect received more attention, and a full description of acute and chronic infarction of the heart was given by Ziegler [31] in his treatise on Pathology; he first used the term "myomalacia cordis" in 1879, affirming its ischæmic origin which had been disputed. In 1884 Leyden [15] published his important paper on the effects of coronary artery disease, in which he gave an accurate pathological and clinical account of coronary thrombosis. A most comprehensive pathological study is to be found in R. Marie's Paris thesis [20] of 1896, which deals with acute necrosis, scarred infarcts, aneurysm, and rupture of the heart; he recognised the frequency of coronary thrombosis and was familiar with its symptomatology. Huchard,[11] in his treatise on angina pectoris, described in the minutest detail the clinical syndrome of cardiac infarction, recognising the "état de mal angineux" and the epigastric site of the pain ("type pseudo-gastralgique"); though his abstract of 185 post-mortem records of angina contains many cases of cardiac infarction, old or recent, and in no less than 31 instances coronary thrombosis is specified, yet he does not suggest the possibility of its clinical distinction from ordinary angina.

In 1905 Kernig [12] first drew attention to the clinical association of pericarditis with anginal pain, described later by Sternberg [27] under the name of "pericarditis epistenocardica." The next important contribution to the subject was that of Obratzow and Strachesko [22] in 1910, describing three cases, confirmed by necropsies, in two of which the diagnosis had been made during life. They appear to have been the first to establish coronary thrombosis as a clinical entity distinct from angina pectoris. Herrick,[10] in 1912, further emphasised this distinction and drew attention to the fact that coronary thrombosis was not always immediately fatal. Since then an extensive and valuable American literature has appeared, and we may mention papers by Wearn,[28] Christian,[3] Fulton,[5] Le Count,[13] Levine,[14] Smith,[26] Acker,[1] Wolff and White,[30] and an excellent review by Hamman [8] among many. Starting with the experimental work of Smith on coronary artery ligation in animals, the effect of coronary thrombosis on the electrocardiogram has been studied, and Pardee [23] first recognised a curve characteristic of the acute stage of myocardial infarction in man. The anatomical studies of Gross on the coronary circulation enlarged our knowledge of the pathology of coronary obstruction. Allbutt [2] discussed coronary thrombosis chiefly as it affected and opposed his view of the aortic origin of angina pectoris. Mackenzie,[19] though not making the clinical distinction from angina, describes typical examples. In this country papers dealing directly with the subject have been published by A. G. Gibson,[7] McNee,[21] and Coombs and Hadfield,[4] and in France by Gallavardin,[6] Lian,[16] and Lutembacher.[18]

Pathology.

In the vast majority of cases the pathological basis of cardiac infarction is atheroma of the coronary arteries. Final occlusion is usually due to thrombosis at the site of constriction or ulceration of the vessel. In 70 per cent. of recent infarcts due to atheroma, thrombosis was visible to the naked eye. In the remaining 30 per cent. no thrombosis was seen, but microscopical examination was not made so that it was impossible to exclude a minute thrombosis as the final factor in an occlusion which had as its primary and essential factor atheroma.

Occasionally cardiac infarction is due to closure of the mouths of the coronary arteries by syphilitic aortitis, with or without thrombosis in addition. Less than 10 per cent. of all cardiac infarcts are due to syphilis in this way, though there are cases in which syphilitic aortitis is present, but where infarction is due to coronary atheroma and thrombosis. Coronary embolism is the rarest cause of gross cardiac infarction, and is then most often a complication of infective endocarditis.

We give below statistics from an analysis of necropsies in 83 cases of cardiac infarction or of mortal coronary thrombosis, 72 of which are from the post-mortem records of the London Hospital during the five years 1922-26.

Recent Infarction (51 Cases).—In 14 of these there was old infarction in addition. The basis of infarction was as follows:—

	Cases.
Coronary atheroma complicated by thrombosis	29
Coronary atheroma without macroscopical thrombosis	11
Syphilitic occlusion of coronary orifices complicated by thrombosis	2
Syphilitic occlusion of coronary orifices without thrombosis	5
Coronary embolism	4

Mortal Coronary Occlusion without Visible Infarction.

Coronary atheroma complicated by thrombosis	7

Old Infarction (25 Cases).

Coronary atheroma complicated by thrombosis	9
Coronary atheroma without macroscopical thrombosis	15
Syphilitic occlusion of coronary orifices	1

Site of Thrombosis.—Including four cases of multiple thrombosis, the left coronary or a branch was involved in 37 instances and the right in 18. In the left coronary the site of thrombosis was as follows:—

	Cases.
Anterior descending branch	24
Circumflex branch	10
Main vessel	3

The site of election for coronary thrombosis was the left anterior descending branch in the first 3 cm. of its course. In eight cases of syphilitic occlusion both coronary orifices were affected in five instances and the right orifice alone in three, twice with thrombosis.

Size and Distribution of the Infarct.—The area infarcted may be no larger than a penny or may include almost the whole of one ventricle. The site of an infarct depends upon the area of muscle supplied by the occluded artery, which may vary considerably in different hearts. The following is the usual distribution. Occlusion of the left anterior descending branch may involve the apex, anterior wall of the left ventricle, anterior part of the interventricular septum, and possibly an adjacent strip of the right ventricle.

Occlusion of the circumflex branch may involve the lateral and posterior walls of the left ventricle, usually including the papillary muscles of the mitral valve. Occlusion of the right coronary may involve the posterior part of the interventricular septum and the posterior walls of both ventricles. Sometimes the right coronary supplies most of the posterior wall of the left ventricle. The infarcted area will generally be less extensive than the total area supplied by the occluded artery.

The infarction is always more extensive on the endocardial aspect than on the pericardial, and often does not involve the subpericardial muscle at all. The earliest evidence of infarction is slight swelling and pallor of the myocardium. Later, at the stage more usually seen, it appears as a sharply demarcated yellow or grey area surrounded by a red injected border, and occasionally there is extensive hæmorrhage into the neighbouring muscle. Sometimes the infarct is diffusely mottled with areas of hæmorrhage, or it may be completely hæmorrhagic (" apoplectic type "). Old infarction is seen as a localised shrunken fibrous patch, suggesting tendon in colour, and related to occlusion of a corresponding coronary branch. It may be limited to the endocardial aspect or involve the whole thickness of the ventricle. There is invariably hollowing of the endocardial surface, but external bulging is rare. We have seen almost complete organisation of an infarct in a case dying six weeks after the onset of the attack. The frequency of old or of multiple cardiac infarction post mortem confirms the growing clinical experience that many individuals survive the infarction for considerable periods.

Cause of Death.—Of the 83 post-mortem cases, including seven cases of coronary occlusion without infarction, the immediate cause of death was cardiac failure in 62, of which 24 (29 per cent.) were brought to hospital dead. In the remaining 21 cases death was partly or entirely due to other causes such as perforated gastric ulcer, strangulated hernia, surgical operations, malignant disease, &c.

Complications.—Rupture of the heart was present in five cases and aneurysmal bulging in five. In one case there was hæmopericardium without complete rupture. Intracardiac thrombosis, embolism, and pericarditis are mentioned later.

The Clinical Syndrome.

Incidence.—Of our cases 93 were males and 7 females. Of the 83 post-mortem cases 72 were males and 11 females. Thus about 90 per cent. of cases of cardiac infarction were males. The maximum age-incidence was between 50 and 70 years, though it was fairly common after 40. In both the cases under 30 coronary embolism was the cause of the infarction. (Table I.)

Table I.

Cases.	Under 20	Age.						Over 80
		20–29	30–39	40–49	50–59	60–69	70–79	
100 clinical..	—	—	2	20	33	35	9	1
82 P.M. ..	1	1	3	11	24	28	14	—

The immediate results of coronary thrombosis are threefold—shock, anginal pain, and symptoms of heart failure. Later certain special symptoms, due to the cardiac infarction, may arise. Any one of the three elements mentioned may predominate; hence the clinical picture varies in different cases. Three fairly distinct clinical groups may be recognised: (1) sudden death at onset; (2) prolonged anginal pain with shock; (3) dyspnœa and failure without severe pain.

1. *Sudden Death at Onset.*—These patients collapse and die with dramatic suddenness; death overtakes them during the ordinary round of daily life, in bed, at work, in the street, at church, or on the golf course. Death is most probably due to the onset of ventricular fibrillation from sudden ischæmia of part of the heart muscle. At the necropsy coronary thrombosis is found, often without visible infarction. Such cases have little clinical interest, and we have excluded them from our clinical series. They are common subjects of coroners' inquests and are often brought into hospital dead (" B.I.D.").

2. *Sudden Onset with Prolonged Anginal Pain and Shock.*—To this group belong the majority of cases in which the diagnosis can be established during life. The patient may have had angina pectoris for years, or may have had neither pain nor any other indication of cardiac disease. The attack proper is sometimes preceded for a few days by twinges of sternal or brachial pain, occurring apart from exertion, and often attributed to rheumatism or indigestion. These prodromal pains herald the beginning of thrombosis, while the attack proper indicates complete occlusion of the artery.

The onset is abrupt. There is agonising pain in the chest accompanied by shock and collapse. The site of the pain is usually sternal, most often in the middle or lower third, sometimes in the epigastrium. It tends to extend more widely over the chest than in ordinary angina, and is not so readily localised by the patient to a single area. Radiation to one or both arms, to the back, and even to the neck and jaw is common at the onset or later, though the pain may remain limited to the lower sternal region. The onset of pain is rarely attributed to exertion; many patients are roused from sleep by pain, or are seized with it while sitting quietly at rest, after a meal, or during a leisurely walk.

In contrast to the rigid immobility seen during angina pectoris the subject of coronary thrombosis often exhibits marked restlessness, and may get out of bed and walk about, or even writhe in agony on the floor. Occasionally actual syncope occurs. With the pain the signs of shock and circulatory failure appear. The expression is anxious and the features may assume an ashen, greyish hue. Sweating is almost invariable and often profuse. Vomiting is usual after the onset and may be repeated for days. Some degree of cyanosis and dyspnœa occur, though dyspnœa may not be a prominent symptom.

Physical examination at this stage reveals little. The temperature is subnormal, the pulse small and scarcely palpable, often rapid, but sometimes normal or even reduced in rate. Usually the rhythm remains normal, but extrasystoles are quite common and in a small proportion an abnormal rhythm is present. The cardiac impulse is feeble or impalpable (unless the heart is greatly enlarged), and the sounds are distant or inaudible. There may be gallop rhythm, but murmurs are rarely heard. Crepitations over the lung bases and enlargement of the liver are early and characteristic signs of heart failure. The blood pressure when first recorded is low, sometimes below 100 mm. systolic.

Course.—The duration of severe pain varies from half an hour to many days; it passes gradually, often leaving a dull ache or soreness and tenderness for a few days. Nitrites give no relief, and in most cases repeated doses of morphia are required. After recovery from the initial shock the temperature rises to 99°–102° F., slight fever persisting perhaps for a week. Leucocytosis up to 20,000 is common, but not invariable. Pericardial friction may be heard within a few days of the onset.

Those who succumb to the attack may die suddenly, often with a recurrence of severe pain, or become increasingly breathless and cyanosed, dying with gross congestive failure in a few days or weeks. Where the attack is not rapidly fatal the immediate course may be that of severe congestive failure with ultimate death or recovery, or else the patient emerges from his prolonged pain without failure, though often with a liability to anginal pain on slight exertion which he may not have had before.

Convalescence is usually slow. The blood pressure rises to normal limits, the heart beat becomes stronger,

the heart sounds get louder, and the patient's colour returns. Tachycardia, if present, may persist for weeks. Embolic complications from intracardiac thrombosis are liable to occur during the first few weeks after the onset; thus there may be pain over the spleen, hæmaturia, hæmoptysis, or signs of cerebral, mesenteric, or peripheral embolism.

Shortly after the attack the heart may appear normal on physical examination and remain so, though the electrocardiogram is often typically abnormal from the first. Nothing is more remarkable than the rapidity with which certain patients can recover from the initial shock and collapse. They may be able to walk about within a few days of the attack, and some may even attempt to resume work despite a recent cardiac infarction. Thus one patient (Case 172), after being in bed for a few days, felt better and got up to go to work. Going down the steps of a public lavatory he collapsed and died. Necropsy revealed a small recent infarct of the left ventricle, with hæmorrhage around the infarcted area and blood leaking into the pericardium. Had he remained in bed he might have recovered. Another patient (Case 76), a male of 47, on waking at 6 A.M., was seized with severe midsternal pain passing down the right arm, accompanied by sweating and faintness, lasting for ten hours, until finally relieved by morphia. The next day only a slight ache remained, and after three days he got up and walked to hospital. There were no abnormal signs in the heart except tachycardia of 110. Temperature 99°. He looked pale and ill. The electrocardiogram was characteristic of recent infarction. We may cite briefly the following two typical cases, the first rapidly succumbing, the second surviving for two years.

CASE 75.—Male aged 65. Had been treated for hyperpiesis; blood pressure 200 systolic. No previous angina, but occasional pain in the chest unrelated to effort. On June 28th, 1926, he was awakened at 3 A.M. by severe pain in the chest and dyspnœa, with sweating. The pain was at the lower end of the sternum and spread across the chest and into both arms; it continued all the next day. When seen at hospital he was pale and breathless. Temperature 99°, later 100° F. Pulse 100, regular. Arteries tortuous. Blood pressure 150/100. Apex beat feeble; sounds normal. Crepitations widespread in chest. No œdema. Dyspnœa increased, Cheyne-Stokes breathing supervened, and he died on the seventh day of his illness. Necropsy: Organising pericarditis round apex; recent infarction of the apex and interventricular septum, with thrombus in the left ventricle over the infarct; severe coronary atheroma and thrombosis of the stenosed left anterior descending branch 2·5 cm. from its origin; pulmonary infarction.

CASE 85.—Male aged 49. No previous angina. On Nov. 1st, 1925, while walking, he was doubled up with sudden severe sternal pain; he vomited repeatedly and sweated. He went to bed, but the pain continued for three days. The next day temperature 100° F.; pulse 100, rising to 120; pain abdominal. He was sent to hospital as an abdominal case. Slight enlargement of heart, sounds distant. B.P. 130/80. Wassermann reaction negative. EC., normal rhythm, left ventricular predominance, low voltage Q R S waves with modified R-T period typical of recent infarction. After two recurrences of pain he recovered. During the next two years he was able to get about, though subject to anginal pain. On Sept. 9th, 1927, nearly two years after his attack, he collapsed in the street and was brought in dead. Necropsy: Extensive old shrunken infarction of the ventricular septum and apex (corresponding to his attack in 1925) and patchy fibrosis of the remaining myocardium. Atheroma of all coronaries and old thrombosis of anterior descending branch. No recent infarction.

Repetitive Seizures.—In the type of case outlined above, once the initial attack is over, there is no immediate return of similar symptoms though milder degrees of pain or "reminders" are common during the first few weeks. In another type the initial seizure is followed by repeated severe exacerbations, sometimes with tachycardia or dyspnœa, each of which may last an hour or more. In such patients the course is protracted and they may remain desperately ill for weeks.

Ingravescent Anginal State.—In some patients, especially those already subject to angina, the symptoms of cardiac infarction are of more gradual onset. The anginal attacks become more frequent and more easily induced, occurring apart from exertion and during the night. The pain lasts longer and is more severe, until after one or more bad attacks a status anginosus supervenes. The patient becomes gravely ill; fever, leucocytosis, fall of blood pressure, and perhaps dyspnœa and œdema follow. Death may be sudden, or gradual from failure, recovery being rare. Such symptoms may arise in cases of gradual coronary occlusion where compensatory collateral circulation is impossible; for instance, in occlusion of the coronary orifices by syphilitic aortitis, as in the following case:—

CASE 183.—Male aged 45. No history of syphilis. He was well until two months previously, when he had his first anginal attack. The attacks became more frequent and more severe, so that he was admitted to hospital. He had frequent bouts of pain at the lower end of the sternum spreading over the whole chest and down both arms, lasting 20 minutes to an hour. No abnormal physical signs were found in the heart. Blood pressure 105/75. Wassermann reaction positive. He appeared to be almost constantly in pain, and after nine days he died suddenly during a nocturnal seizure. Necropsy: Syphilitic aortitis with great stenosis of the mouths of both coronary arteries; recent infarction involving the papillary muscle of the aortic cusp of the mitral valve. Microscopically fibrosis and recent necrosis of the myocardium.

3. *Dyspnœa and Failure without Pain.*—When infarction supervenes in a case with pre-existing signs and symptoms of heart failure the clinical picture may be less distinctive. Pain is not a prominent symptom; it is either absent or quite overshadowed by dyspnœa. A sudden exacerbation of the signs of failure may be the only evidence of cardiac infarction. Gallavardin,[6] especially, has drawn attention to the fact that patients may die of infarction of the heart without ever suffering pain. There may be some "tightness" or "oppression" in the chest. Thus one patient (Case 178) complained to his friends of the sudden onset of breathlessness, and decided to go to hospital next day, but while walking in the vicinity of the hospital he collapsed and died. Necropsy showed severe atheroma and syphilitic aortitis, with aortic incompetence and stenosis. The coronaries were atheromatous, the left circumflex branch was thrombosed, and there was recent infarction of the left ventricle. Another patient (Case 139), aged 65, had been under treatment for hyperpiesis and heart failure. Seven months previously he had had sudden attacks of dyspnœa with a sensation of weight in the chest, lasting for a week. He was seen with a recurrence of severe dyspnœa, and this was followed by congestive failure, hæmoptysis, and fever; he died in two weeks. At the necropsy there was old fibrous infarction of the posterior wall of the left ventricle (corresponding to the first attack of dyspnœa), and recent necrosis of the interventricular septum. The left circumflex branch was completely occluded by atheroma and the left anterior descending branch was stenosed.

Special Clinical Features.

Onset.—In 33 cases the pain began during sleep or in bed, often in the early hours of the morning, and in another 26 cases at home quite apart from exertion. In 22 cases it began during some habitual form of exertion. In the remaining 19 cases details of onset are wanting. Thus in over half the cases the onset of pain was unrelated to effort.

Site of Pain.—In 68 cases the pain was sternal, being at the lower half or in the epigastrium in 43, at the upper half in 9, and recorded simply as sternal in 16. In the remainder the pain in the chest was either widespread or situated abnormally. In 28 cases there was radiation to both arms, in 25 to the left arm alone, and in 8 to the right arm alone. In several the main site of pain was in the back between the scapulæ. As in ordinary angina, the pain may start in the neck or arms before settling at the sternum. Generally speaking the pain was more often at the xiphisternum, more often bilateral, and more widespread than in ordinary anginal attacks.

Duration.—Pain was usually cut short or relieved by morphia, leaving a dull pain or discomfort for days. Recurrences were fairly common. The duration of severe pain in our cases was as follows: 1–6 hours in 41 cases, 6–24 hours in 24 cases, 1–3 days in 22 cases, and longer than three days in 13 cases.

Blood Pressure.—A fall of blood pressure follows cardiac infarction. We have commonly found the systolic level between 90 and 120 mm. within a few days of the attack, the lowest figure being 75 mm. Where there is a pre-existing hyperpiesis the blood pressure may fall and yet be relatively high, and we have observed systolic pressures of 150–170 mm. in such shortly after the onset of infarction; there may then be a further fall or a slight rise corresponding to the degree of recovery. In a few cases, under observation prior to coronary thrombosis, we were able to measure the fall of pressure. Thus in one patient the systolic pressure which before coronary thrombosis had been 200 mm. remained as high as 150 mm. after the attack, though at necropsy a large infarction of the left ventricle was found. In another, whose pre-existing systolic pressure had been 260 mm., it was 200 shortly after the onset of pain and three days later had fallen to 130; five months after recovery it was 190 mm.

Leucocytosis.—Where blood counts were obtained shortly after infarction we found a leucocytosis of 10,000–15,000 common, but not invariable; the highest leucocyte count was 25,800. According to Libman and Sacks[17] leucocytosis may develop as early as one and a quarter hours after the onset of symptoms. They found a leucocytosis of 15,000–20,000 in more than half their cases. We have found fever a more useful diagnostic sign of infarction than leucocytosis.

Fever.—During the stage of initial shock the temperature is subnormal and may remain so in fatal cases. In the majority there is a rise of temperature to 99–102° F. within the first two days, slight fever persisting for 3–10 days. A typical temperature chart is seen in Fig. 1.

Pulse.—A moderate degree of tachycardia, up to 100 a minute, is a common sequel of cardiac infarction, but occasionally a tachycardia of 120 or higher may persist for weeks. The pulse may, strange to say, remain normal in rate even with severe symptoms or in mortal cases, and a sinus bradycardia of 40–60 was recorded more than once. An irregular pulse from extrasystoles was very common either at the onset or subsequently, but abnormal rhythms only occurred in 14 per cent.

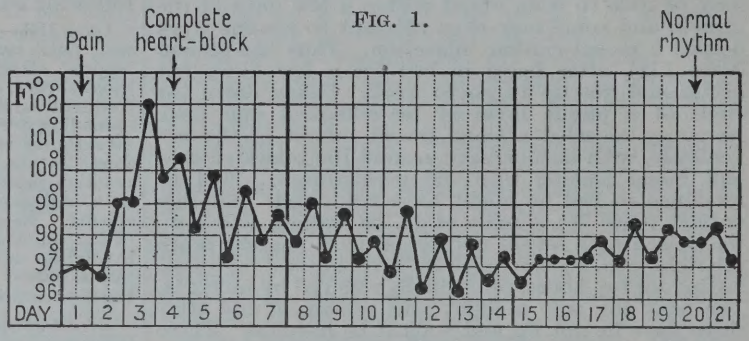
Complications.

Pericarditis.—In our 83 post-mortem records pericarditis was noted in only 11 (13 per cent.). In the 100 cases seen clinically pericardial friction was heard in seven. Usually pericarditis is limited to a small area over the infarction, but it may be generalised, though effusion is rare. In one patient an X ray did show pericardial effusion ten days after the onset of infarction; at the necropsy there was generalised fibrinous pericarditis with 12 oz. of blood-stained effusion, thrombosis of the left circumflex coronary, and infarction of the left ventricle. The infrequency of pericarditis rests on the fact that infarction usually involves the endocardial aspect of the heart, and is often separated from the pericardium by a layer of muscle which obtains a blood-supply from the epicardial vascular network. In some specimens we have examined, adiposis of the pericardium rendered the infarction invisible from the surface.

Intracardiac Thrombosis and Embolism.—Intraventricular thrombus formation over the necrosed muscle is a serious complication of cardiac infarction, for detachment of a clot may lead to embolism. Where the septum is affected the thrombosis may involve both ventricles, so that both pulmonary and systemic embolism may result. Embolic symptoms occur most often within the first few weeks of infarction.

Intracardiac thrombosis was noted in 14 of the 83 necropsies; there was evidence of embolism, old or recent, in 16 cases (3 with infective endocarditis), as follows: renal in 9 cases, splenic in 8, pulmonary in 7, mesenteric in 3, peripheral in 2, cerebral in 1, and abdominal aorta in 1. In our clinical series embolism occurred in 8 cases, as follows: pulmonary 3, cerebral 3, renal 1, splenic 1. The following is an example of multiple embolism following intracardiac thrombosis over an infarction.

FIG. 1.



Temperature chart after coronary thrombosis, showing subnormal temperature followed by pyrexia. Incidentally complete heart-block was recorded on the fourth day (Case 8).

CASE 171.—Male aged 54. Came to hospital complaining of pain in the right calf. Twelve days previously he had wakened in a cold sweat with severe tightness in the chest and had fainted. He remained in bed; four days later he had sudden agonising pain in the right calf and the leg became cold and numb. When seen at hospital there were signs of gangrene of the right leg. Temperature 102° F. No abnormal signs in the heart; pulse 110, regular; blood pressure 125/75. Amputation was performed through the right thigh. Three days afterwards the left leg became cold and mottled, the pulse became rapid and feeble, and on the twenty-ninth day of his illness he died. Necropsy: Coronary atheroma with thrombosis of the left anterior descending branch and recent infarction of the left ventricle and septum; adherent granular thrombus in both ventricles over the infarction. Embolic thrombus in the superior mesenteric, right external iliac and femoral, and splenic arteries, and hæmorrhagic infarction of the small intestine, infarction of the spleen and of both kidneys.

Thrombosis Elsewhere.—In three of our cases phlebitis with thrombosis of leg veins complicated the attack of coronary thrombosis. Occasionally the onset of coronary thrombosis appeared to be related to infection, such as carbuncle, or sepsis elsewhere.

Abnormal Rhythms.—In most cases of cardiac infarction the rhythm remains normal. Extrasystoles are very common, usually ventricular, sometimes arising from more than one focus in the ventricles, as shown by electrocardiograms. Auricular and nodal extrasystoles have been seen. In 14 cases cardiac infarction induced an abnormal rhythm, as follows:—

	Cases.		Cases.
Paroxysmal tachycardia	2	Paroxysmal flutter and fibrillation	1
Paroxysmal fibrillation	5	Partial heart-block ..	1
Paroxysmal tachycardia and fibrillation ..	1	Complete heart-block ..	1
Paroxysmal flutter ..	3		

Acute heart-block following cardiac infarction is of great interest and may be associated with Adams-Stokes attacks. It may be transient and completely disappear if the patient recovers, as in the following instance.

CASE 8.—Male aged 55. First seen in September, 1913. After a week of prodromal anginal attacks he had a severe seizure of midsternal pain lasting 24 hours, with fever (Fig. 1), vomiting, and cyanosis. Heart clinically normal, sounds distant. Arteries thickened. Wassermann reaction negative. The pulse was irregular and polygrams showed partial block; later the pulse became slow and regular,

rate 40, and polygrams showed complete block. He recovered completely and normal rhythm returned. Electrocardiograms in October, 1913, showed T inversion characteristic of cardiac infarction. He died in February, 1925, 11½ years after his attack, with signs of bronchitis.

We have described elsewhere the three cases of flutter due to cardiac infarction.[24] The association of paroxysmal ventricular tachycardia with cardiac infarction has been described by Robinson and Herrmann.[25] In our three cases of paroxysmal tachycardia electrocardiograms were obtained in two, one probably ventricular, the other nodal. In one of our post-mortem series curves of ventricular tachycardia had been obtained.

An abnormal rhythm involving tachycardia is a serious additional embarrassment to the heart, but fortunately these paroxysms are often short, and in the case of flutter or fibrillation can be treated by digitalis. Normal rhythm returned in all our 14 cases. Once paroxysms of fibrillation continued after recovery and eventually fibrillation became established.

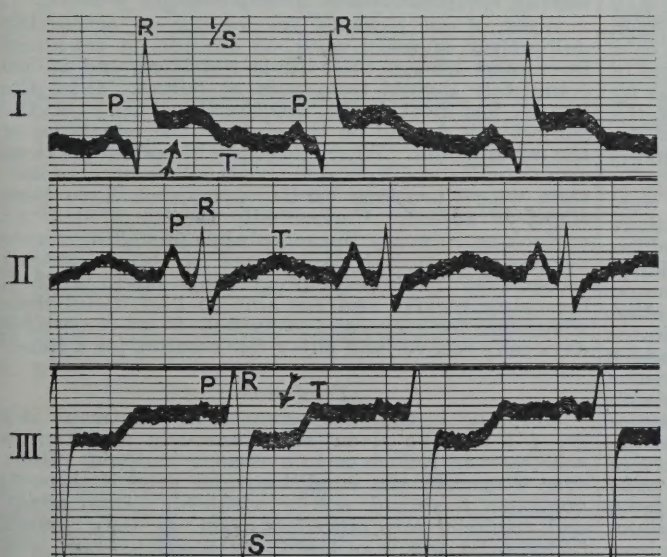
Physical Signs of Underlying Cardiovascular Disease.

In view of its pathology the clinical quest in coronary thrombosis is for signs of general arterial disease and of aortic atheroma or syphilis. In many patients with coronary atheroma the peripheral arteries seem normal, though signs of aortic atheroma, such as a rough aortic systolic murmur with a loud second sound, are often found. X ray examination is an invaluable means of demonstrating aortic atheroma.

Coronary disease alone can cause some degree of hypertrophy of the heart, especially of the left ventricle; but unless high blood pressure or valvular disease is present in addition, cardiac enlargement is not a feature. The fall of blood pressure which follows myocardial infarction can mask an underlying hyperpiesis, and this should be suspected whenever the heart is really large. The clinical findings in our 100 cases were as follows:—

	Cases.
X ray examination {Aorta normal, 29 / „ enlarged, 39}	68
Clinical evidence of aortic atheroma	26
Peripheral arterial thickening	36
Intermittent claudication (2 with gangrene of toes) ..	8
Syphilis (certain)	5
„ (doubtful)	5
Hyperpiesis (B.P. 200 or more) apart from attack ..	15
Moderate hypertension (150–200)	34

FIG. 2.

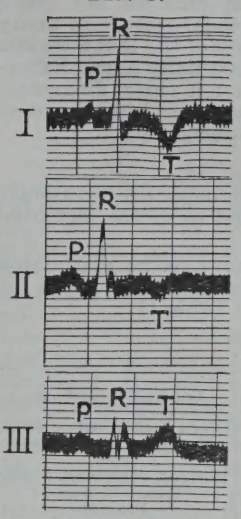


Electrocardiogram taken four days after coronary thrombosis, showing plateau type of curve; the R-T period is elevated in lead I. and depressed in lead III., as indicated by arrows (Case 79).

Relation to Angina Pectoris.

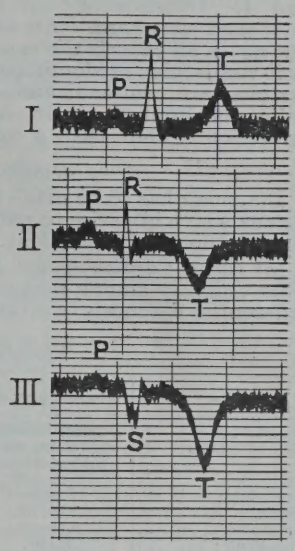
The incidence of previous angina was as follows: previous typical angina, 45 cases; previous atypical pain, 8 cases; prodromal angina only, 9 cases; no previous angina, 38 cases. Which means that half those who get cardiac infarction have never suffered from angina until the onset of their attack or immediately before it.

FIG. 3.



Electrocardiogram taken three weeks after coronary thrombosis, showing inversion of T wave in lead I. and also in lead II. (Case 66).

FIG. 4.



Electrocardiogram taken two and a half weeks after coronary thrombosis, showing inversion of T wave in lead III. and also in lead II. (Case 82).

Coronary thrombosis may initiate angina pectoris, complicate its course, or prove the fatal termination. It is increasingly clear, both on pathological and clinical grounds, that many patients hitherto considered simply as cases of angina pectoris are actually suffering from a past coronary thrombosis. In other words, we are witnessing a splitting up of angina pectoris into two component parts, which clarifies its pathology. First, the group in which coronary occlusion is a gradual process from atheroma or syphilis and leads to scattered myocardial fibrosis, and in which the clinical history is of anginal pain on exertion becoming more frequent and more easily induced with the passage of time. Secondly, the group in which, at the onset or during the course, an acute infarction occurs, usually from coronary thrombosis, and in which the history includes one or more of the outstanding attacks we have described. If the attack is not too remote the electrocardiograph will often confirm the diagnosis. We cannot discuss here the various theories which have been advanced to explain the causation of anginal pain, but we believe that the study of coronary thrombosis has nailed angina for ever to the tree of decaying coronary arteries.

The Electrocardiogram.

As a rule the electrocardiogram after cardiac infarction is characteristic, and occasionally it provides the only objective sign of a cardiac lesion. Fig. 2 shows a typical curve taken four days after the onset of symptoms. The diagnostic feature is the absence of an iso-electric period between the R S and T waves, so that a plateau type of curve results in which the R-T interval is either elevated or depressed.[23] After a few weeks characteristic changes in the T waves are

usually seen. There is a deep inversion of T in either lead I. or lead III., together with a lesser degree of inversion or flattening of T in lead II. These inverted T waves are sharply pointed and often of large amplitude. Typical curves are seen in Figs. 3 and 4. Observations on these changes are being published elsewhere. An additional feature in many but not in all cases is the small size of the Q R S waves. Left ventricular predominance is usually seen. Extrasystoles are common, and, though their diagnostic value is limited, their occurrence after cardiac infarction is more than a coincidence.

Diagnosis.

Diagnosis has to be made from other cardiovascular lesions which give rise to pain and dyspnœa and from acute abdominal conditions.

(*a*) *Other Cardiovascular Lesions.*—The distinction from ordinary angina pectoris is not difficult, and the differential diagnosis is given in Table II.

TABLE II.

—	Angina pectoris.	Cardiac infarction.
Onset	During exertion.	Often during rest or sleep.
Site of pain	Sternum, often mid-sternum.	Sternum, often lower third.
Attitude	Immobile.	Restive, even walk about.
Duration	Minutes.	Hours or days.
Shock	Absent.	Present.
Dyspnœa	Absent.	Often present.
Vomiting	Rare.	Common.
Pulse	Unchanged.	Small, often rapid.
Temperature	No fever.	Fever follows.
Blood pressure	Normal or rise.	Fall.
Heart sounds	Normal.	Distant, sometimes gallop, or pericardial rub.
Congestive failure	Absent.	Commonly follows.
Electrocardiogram	Often abnormal.	Usually diagnostic.

Intrapericardial rupture of the aorta may closely simulate coronary thrombosis, but always proves fatal. More important is the distinction from paroxysmal dyspnœa of cardiovascular disease in which there may be oppression in the chest; the persistence of high blood pressure and the predominance of dyspnœa over pain suggest paroxysmal dyspnœa. Acute œdema of the lungs has been confused with angina pectoris by some French writers (angina of decubitus). When the patient is restless and the pain too prolonged for ordinary angina we have seen coronary thrombosis diagnosed as neurosis.

(*b*) *Abdominal Conditions.*—Six of our patients were admitted to hospital as surgical cases, and in others abdominal disease was at first suspected. Sudden severe epigastric pain, with tenderness and rigidity, vomiting, shock, and a small rapid pulse are common manifestations of cardiac infarction, and must often suggest such conditions as perforated gastric or duodenal ulcer, acute pancreatitis, or gall-bladder disease. Careful inquiry should be made for previous anginal pain as opposed to gastric pain, and a search made for evidence of heart failure. An electrocardiogram may settle the question. In doubtful cases the following point to a cardiac origin: (1) a history of previous sternal pain on exertion, relieved by rest; (2) radiation of the pain to the arms, neck, or jaws, at the onset or in previous attacks; (3) signs of failure, such as dyspnœa, cyanosis, crepitations at the lung bases, enlargement of the liver, or œdema. A patient may actually have chronic peptic ulcer as well as coronary atheroma, when there will be a history of both gastric and anginal pain. One of our patients (Case 81) died of perforated duodenal ulcer six weeks after a typical attack of cardiac infarction which was confirmed post mortem. In 8 of our 83 post-mortem cases (10 per cent.) there was chronic gastric or duodenal ulcer, a fact suggesting an ischæmic origin for some such ulcers.

Course and Prognosis.

Of our 100 cases 31 have died, one not traced is probably dead, and 68 are still alive. Twelve patients died within a month of the attack, 11 in 1–6 months, 7 in 6–24 months, and 1 after 11½ years, the average duration of life being six months in these 31 patients who died. Of the 68 known to be still alive the duration of life after the attack has *so far* been longer than five years in two cases, 2–5 years in 9, 1–2 years in 19, 6–12 months in 16, 1–6 months in 20, and less than a month in 2, the average being just over 13 months. The average survival period up to date for the whole series is just under 11 months, but this will be much longer when all cases have been followed to their termination. In White's [29] series of 62 cases of coronary thrombosis, of which half were alive at the time of reporting, the average survival period was 20 months. Our figures do not indicate the full mortality of coronary thrombosis as our series does not include those dying at the very onset. On pathological as well as on clinical grounds, we can confidently assert that a patient seen alive with coronary thrombosis is more likely to survive than to succumb to the attack. Old healed infarction is almost as frequent a pathological finding as acute necrosis, though a far higher proportion of cases of recent infarction come to post-mortem for a coroner's inquest. There must be every grade of infarction, according to the calibre of the occluded vessel, the largest proving rapidly fatal, the smallest passing unrecognised during life, though we think that any large scar found in the heart must have had its counterpart in the clinical course.

In giving a prognosis in a case of severe anginal pain it is essential to differentiate between coronary thrombosis and a bad attack of ordinary angina pectoris. Urgent symptoms may arise from a small infarction; but this can heal and thus allow of improvement, whereas in severe angina from progressive and relentless coronary disease change can only be for the worse. Sudden death may ensue within a few hours or days in any type of case; the additional risk from embolism becomes remote after a few weeks. If pain is prolonged and resistant to morphia, if dyspnœa is intense, or if congestive failure progresses rapidly the prognosis is correspondingly worse.

Eight of our patients are leading an active life doing their ordinary work, 33 are able to get about in comfort though their life is restricted, and 25 are completely invalid from pain or failure. Once the infarct has healed the functional capacity of the subject will depend on the state of the remainder of the myocardium. Where there is a history of previous severe angina or dyspnœa recovery will be less complete than where previous cardiac symptoms have been slight or absent. Undoubtedly far too gloomy an outlook on coronary thrombosis has prevailed, largely because non-mortal cases have so often escaped recognition. A hopeful prognosis is often justified, for many survive and are able to lead useful lives sometimes for years, and even those in grave peril for days may recover and enjoy fair comfort for a time.

Treatment.

Morphine is the first essential in treatment and gr. ¼–½ may be given subcutaneously as often as necessary to reduce or to overcome the pain. However desperate the condition, and even if there is vomiting, it should not be withheld. Amyl nitrite and trinitrin are powerless, and as they induce tachycardia and may lower the blood pressure still further they are expressly contra-indicated. Complete physical rest is the next essential in treatment. All preparations for a serious and lengthy illness should be made at once.

Digitalis for the first time finds a place in the treatment of cardiac pain, for it can reduce the pulse-rate and relieve the congestive failure which may accompany or follow the pain of cardiac infarction. In several of our cases it was definitely beneficial in this way. If symptoms or signs of failure appear, and they should be looked for, a dose of ℥ xx. of the tincture, four-hourly for six doses, would be suitable, followed by ℥ x.–xx., three times a day. Remembering the state of the myocardium, we shall studiously avoid toxic effects. Paroxysms of flutter or fibrillation may be

treated similarly, if not by strophanthin intravenously (gr. 1/200–1/100). Even in simple or in paroxysmal tachycardia in these circumstances digitalis may be tried.

Absolute rest in bed for not less than a month is imperative to allow healing of the infarct and to reduce the risk of embolism. The subsequent management will be that of a patient known to be arteriosclerotic and prone to anginal pain, though the probability of another cardiac infarction is not great. Convalescence will therefore be prolonged and the return to ordinary life postponed as long as possible. If exertion is restricted to less than that which induces pain greater capacity may ultimately be obtained.

It is a pleasure to express our indebtedness to the staff of the Pathological Institute of the London Hospital. Prof. H. M. Turnbull, Dr. W. W. Woods, and Dr. A. B. Bratton have taken great trouble in examining specimens and sections and in collaborating in the pathological portion of this paper. Colleagues on the medical staff and in practice have kindly helped with clinical cases and details; we thank Lord Dawson, the Medical Unit (Prof. A. W. M. Ellis), and Dr. R. A. Rowlands for permission to publish particular cases, and Dr. G. T. Western for the Wassermann reports.

COST OF MANCHESTER HOSPITAL SERVICE.—"The Good Samaritan," the year-book of the Manchester and Salford Medical Charities, for 1927, contains a remarkable statement as to the cost of treatment in the hospitals of those two boroughs. The average cost per head of population in England and Wales is 3*s.* 10½*d.*; in Manchester and Salford it is 7*s.* 8½*d.* The explanation suggested is that they are great hospital centres offering unusual facilities for treatment, and that within their borders the conditions of life are such as to increase the incidence of disease and accident.

MOTORISTS AND HOSPITALS.—Beginning with Jan. 1st every motorist who takes out a driving licence in Sheffield is to be asked to contribute a shilling to the funds of the Sheffield Joint Hospitals Council. It is believed that £2000 a year can be raised in this way. When this voluntary tax is paid the licence will be stamped "Sheffield Hospitals Council: Traffic Casualty Fund." At the Royal Hospital and the Royal Infirmary last year close upon 6000 people were treated for injuries caused by street accidents. About 600 were admitted to the wards, at an estimated cost of £10 per patient.

THE ÆTIOLOGY AND TREATMENT OF ACUTE POLIOMYELITIS.*

BY S. A. KINNIER WILSON, M.D. EDIN., F.R.C.P. LOND.,
PHYSICIAN FOR OUT-PATIENTS, NATIONAL HOSPITAL, QUEEN SQUARE; NEUROLOGIST, KING'S COLLEGE HOSPITAL; CONSULTING NEUROLOGIST TO THE METROPOLITAN ASYLUMS BOARD.

FOR several reasons poliomyelitis always awakens concern on the part of the clinician. He cannot foretell, in a given case, whether disabling sequelæ will make their appearance in moderate or in aggravated form, nor from the prodromal symptoms can he determine whether involvement or escape is to be the outcome. No definite relation has as yet been established between the mildness or otherwise of the initial syndrome and of the paralytic consequences. Even if continued paralysis is found in but 25 per cent. of all cases he does not know which are to exhibit this unenviable prominence. In one clinical type the early febrile manifestations are so trifling as practically to escape notice, but the fulminant onset of palsy in some of these emphasises afresh the serious nature of the disease's uncertainties. When invasion of the nervous system is apparent the outlook remains still indeterminate, since residual incapacity is not always proportionate to intensity of early paralysis, while cases are known of a relapsing type, in which fresh palsies appear at appreciable intervals.

Poliomyelitis presents all the characters of a specific infection, and seems to be definitely independent of any other. When rare cases occur of poliomyelitic symptoms supervening in the course of some fever or exanthem of recognised class they are to be regarded either as a coincidence—the fever ostensibly providing a favourable opportunity for the invasion of the virus of the other—or as offering a superficial resemblance to genuine poliomyelitis, but caused in reality by the exceptional localisation and action of the febrile virus, whichever it may happen to be. For example, I have had under care recently a severe case of "poliomyelitis following measles," in which examination has satisfied me that the condition has been in fact a partial transverse myelitis of the rare morbillous type. That other agents than the virus of Heine-Medin's disease can produce an acute atrophic palsy must not be overlooked.

Incidence.

From compilation of numerous and diverse statistics (which need not be cited here) it can be shown that over 75 per cent. of all cases, epidemic and sporadic, develop in children who have not passed the age of 9 years; in the New York epidemic of 1916 no less than 83 per cent. were under 5.[1] A further interesting point emerges, that in the more severe epidemic outbreaks the incidence on youths and adults tends on the whole, though not with regularity, to increase in comparison with that of sporadic outbreaks. In respect of the earliest years of life the disease affects children of each of the first three with a certain equality; of those cases that begin in the first year a majority develop during the second six months. Congenital poliomyelitis is probably non-existent, though the possibility of intra-uterine infection has been discussed by Batten[2] and others. A case is known in an infant 12 days old (Gunewardene[3])—as far as I have been able to discover, the earliest on record; at the other extreme it has been seen at 54 (Krabbe[4]), and even, apparently, at 67 (Gombault).

The disease has appeared at intervals all over the world, nor has it spared the coloured races. In 1909 an outbreak occurred in Cuba, affecting 140 persons; in 72 cases in which the race was specified 60 were whites, 4 half-castes, and 8 negroes. The Melanesian island of Nauru in the Pacific was visited in January,

* Opening paper at a discussion at the Harveian Society of London, Nov. 17th, 1927.

1909 [5]; 470 cases developed in natives of the island; the majority of the remainder of the total 700 cases were those of imported labourers from the Caroline islands; imported Chinese were unaffected, and only three Europeans out of 80 whites suffered. By way of contrast, however, I may point out that of the 752 New York cases of 1907 [6] only two occurred in coloured children, yet in proportion to the population there should have been something like 14. It is impossible not to feel that these apparent anomalies of infection can be explained only by considerations of direct or indirect openness to attack and of acquired or natural immunity, which must differ materially in different epidemic visitations.

Age is seemingly the sole predisposing factor; inherited and familial "tendencies" can be quite left out of account. Neuropathic "taint" has no significance, since the affection often seizes juveniles who are physically and mentally robust—an observation made by Heine [7] as long ago as 1840 and often commented on since. Family involvement varies considerably also in different epidemics; among the 752 New York cases (1907) there was only one instance of three members of a family being attacked, whereas Trethowan's [8] figures for the Swedish epidemic of 1911 differ one might think fundamentally.

Cases in each family	1	2	3	4	5	6	7	8
Number of families	456	93	46	21	8	2	1	2

In no less than 31 families two to four cases occurred on the same day, and somewhat analogous figures are furnished by Wickman.[9]

The practitioner ought to bear in mind that poliomyelitis is constantly endemic in Great Britain, as in other countries, near and far; I append official figures for 1925.

—	England and Wales.	France.	Germany.	United States.
January	26	10	17	132
February	23	18	28	98
March	17	16	21	89
April	12	17	18	106
May	16	11	25	104
June	15	8	18	254
July	17	15	20	805
August	28	39	31	1428
September	61	19	57	1359
October	57	25	53	932
November	44	20	45	341
December	28	24	37	161

From this table the pre-eminence of infection in the summer and autumn months appears clearly, especially late summer and early autumn, and this feature has been reproduced in by far the greater number of the many epidemics that have been recorded; it receives corroboration from the development of Australian outbreaks in their autumn months of March and April. Such epidemics may extend into the winter months, none the less, a point of significance when the remarkable resistance to cold shown by the virus is carried in mind, and not without bearing on the fashion of spread of the disease.

Transmission of Infection.

Vexed questions of consummate epidemiological importance still obscure our knowledge in respect of the modes of infection. We may note, in the first place, that apart from the production of experimental poliomyelitis in monkeys (and in certain genera only, be it specially remarked) no satisfactory proof of its specific occurrence in domestic animals is forthcoming; hence the occasional reports of synchronous infective maladies in chickens, horses, &c., during epidemic appearances of the human disease can be discounted. Elaborate tests conducted at various times exclude the likelihood of flies, fleas, bugs, or lice playing any part in communicability. Experimental transmission by means of the bite of the stable-fly, *Stomoxys calcitrans*, demonstrated by Rosenow in 1912, is now discredited, nor has the virus been found in the blood of affected subjects. Whether it may adhere to inanimate objects is not fully known, though some evidence points in this direction; Neustadter and Thro [10] succeeded in inoculating monkeys by using dust from the sick room (their work has not been confirmed); carriage of infection by a picture is mentioned by Wickman. Drinking-water, milk, fruit, other articles of food, and numerous other possibilities in respect of modes of transmission have all been scrutinised at one time or another and proved more or less consistently negative. Poliomyelitis has frequently developed in infants purely breast-fed. However, in a small epidemic of eight cases at Cortland, N.Y. (Knapp, Godfrey, and Aycock [11]), the individuals affected all drank milk from a farm at which a case of poliomyelitis had occurred in a youth of 16, who actually continued milking some of the cows while he was in the acute stage of the disease. This is presumably an instance of accidental contamination of milk and of transmission thereby, and it is significant out of proportion to the rarity of the occurrence, since it proves that case-to-case infection is not the sole means of dissemination.

By common consent, as I consider, and more especially since the researches of Wickman, direct contagion from one human being to another is now accepted as the main though not actually the unique means of spread. Whether this is effected by direct contact through breath, clothes, or otherwise, or by indirect contact via carriers, is still as obscure as in the case of various other fevers, but the fact remains. Evidence has steadily accumulated pointing to the existence of the virus in the nasal, buccal, or faucial mucosa of individuals who may or may not develop the disease; in other words, carriers (themselves mostly though not constantly immune) harbour the infection and transmit it on occasion, and are possibly more numerous than actual cases. The often-cited experience of Kling, Petterson, and Wernstedt [12] revealed the existence of 18 carriers among the non-infected members of six families, in each of which only one person suffered. Whether active carriers of a really chronic kind are to be found has not yet been satisfactorily demonstrated, and has been surmised rather than proved by some who favour the carrier theory to the exclusion of other modes of propagation; according to Flexner and Amoss the virus disappears from the nasopharynx within a few weeks.

Carriers notwithstanding, contagion, when all germane data are taken into consideration, must certainly be regarded as relatively rare. The disease, ordinarily speaking, never runs riot. Clinical evidence against indiscriminate spread in schools, hospitals, institutions, and closed communities of any kind is direct and overwhelming. In one of the Massachusetts epidemics only 35 patients out of 150 cases were attending school, and of the 35 no less than 22 attended different schools. Bed-to-bed infection in hospital has never been regarded as other than a negligible risk. Spontaneous infection of experimental monkeys has never been recorded, and no instance of the development of the disease in those whose duties have required them to handle such laboratory animals is known.

When, therefore, the question of infection is reviewed as a whole, and in the light of the illustrations selected for this paper (to which I might readily add) its peculiarities and anomalies must at once strike the critical mind. On theoretical grounds individual susceptibility should depend on whether an abortive attack has occurred in infancy, conferring protection when infection is rife, or on "natural immunity." In respect of the former, doubtless one or other "cold" or "catarrh" or "feverish turn" may as a fact have been an incomplete or abortive attack of endemic poliomyelitis, though unless the epidemic variety is about at the time such trifling illness can scarcely ever be adjudged to have been in reality poliomyelitic. As for the latter, we are not yet in a position to analyse natural immunity objectively. Of obvious importance is the matter of the duration of the infec-

tious stage in a given case; unfortunately definite and unmistakable facts and figures are very difficult to come by in this connexion. Yet how much that is still obscure hinges on it. That both abortive cases and healthy virus-carriers must be a menace seems undeniable, hence isolation of affected patients seems indispensable; yet, as we have seen, infection never appears to proceed regularly from one contact to another in an unending series. My own experience, in more than one family circle, has given me the impression that direct infectivity is at its maximum during the incubating and preparalytic stage, and that once the virus has reached the nervous system, as revealed by the usual nervous symptoms, it ipso facto becomes tucked away, so to speak, in the deeper-seated tissues of the individual concerned and is less communicable; he is less infective. If carriers are infective, as is allowed, they bear the virus in a state of activity superficially, one might say, on their person—not in its recesses; hence the possibility of spread of contagion by means of "droplets" of virus-bearing mucus (as Dudley [13] thinks), or otherwise. Were support to be lent to this view by substantial investigations it might explain comfortably the fact that since patients admitted to hospital wards have usually reached the stage of paralysis indiscriminate spread *never* takes place there. I have not discovered any direct observations on the specific point whether germination of the virus in the nervous system is accompanied by its attenuation or disappearance from the upper respiratory passages; inquiries of this kind would surely repay the highly technical labour they must entail. Of course, I am well aware of the difficulty in respect of familial infection; two members may have been infected with more or less simultaneity from a common source and not from one another.

Practical Considerations.

It will be acknowledged, then, I think, that we have not reached a stage when contradictory pronouncements by different authorities are no longer to be expected. Regrettable as they may appear, especially when public anxiety is aroused, they are no more than legitimate deductions from personal experience; different view-points are adopted only because knowledge is still imperfect. It has been my practice to advise and act along the following lines:—

1. A patient in whom the disease is developing (it is unnecessary to give here the objective data on which reliance may be placed for early diagnosis) is infective, and as such must be isolated. Though he may not transmit the disease to another person he may make him a carrier, and this possibility must be guarded against.

2. A patient who has run the risk of infection and whose case may be purely abortive is equally infective and similar precautions are desirable with him.

3. A patient in whom paralytic phenomena have appeared is possibly (probably ?) past the stage of infectivity by direct contact.

4. A person who has come in contact with a poliomyelitic patient when the latter is incubating or developing the affection may show no symptoms, early or late, but nevertheless should regard himself as a possible conveyer of infection and as such should adopt prophylactic treatment.

5. The incubation period being fairly well established within the average limits of two to ten days, and less certainly extending on occasion to a fortnight, contacts may be regarded as having passed out of danger *to themselves* in three weeks (this period was adopted by many Swedish physicians in their epidemics and seems to have proved satisfactory).

6. How long, however, contacts may constitute a danger *to others* is more difficult to estimate. I have quoted Flexner and Amoss to the effect that the virus disappears from the mucosæ within a few weeks.

Until more is known in reference to this latter point contacts who become carriers remain potential mischief-makers, seeing that their effective segregation over a period of, say, two months presents almost insuperable difficulties. It will be gathered from the sketch given of the tactics to adopt, that attention must be paid to the problems offered by patient developing the disease, by abortive case, and by healthy contact respectively.

Means of Treatment.

We may now pass to a consideration of some aspects of the therapeutic difficulties presented by this disconcerting disease.

Obviously, in the case of all contacts, an effort must be made to destroy the infecting germs, harboured as they definitely seem to be in the upper respiratory passages. Frequent disinfection of nose and throat with douches or gargles of potassium permanganate (1 in 5000), peroxide of hydrogen (1 per cent.), liq. sod. chlorin. (0·5 per cent.) or some other chlorine-containing preparation is advisable. Similar procedure should, of course, be undertaken with increased vigour in any cases beginning to show signs of prodromal infection. Once paralytic symptoms develop they are valueless.

The sole *specific* treatment consists in intraspinous injection of immune serum, a method which has been used with moderate success (Netter,[14] Batten,[15] Amoss and Chesney [16]; cf. also Draper,[17] Flexner and Amoss [18]). An attack of poliomyelitis confers immunity for years, the patient's serum remaining active indefinitely, so that if a suitable convalescent can be obtained the method is simple enough. From some 30 c.cm. of the giver's blood, obtained by venepuncture, the serum is separated, warmed, and injected into the spinal theca by the lumbar route in amount corresponding to the quantity of fluid withdrawn, say, from 4 to 12 c.cm., and this treatment can be adopted daily for some days, commencing immediately the diagnosis is made, and if possible in the preparalytic stage. The practical difficulty is, however, at once apparent—viz., to find an appropriate convalescent or old case at hand precisely when the need arises, since the treatment is valueless for cases that are subsiding.

One reason, perhaps the chief, for delay in connexion with *animal sera* is the difficulty of controlling experimental results in the monkey. Once induced, the experimental disease is much more fatal than the human disease, and attenuation of the virus for therapeutic purposes has not yet been satisfactorily accomplished. With some other human strains, on the contrary, the monkey cannot be infected at all, or else they so quickly lose their power of inducing the disease as to be equally valueless. Until better control of the virus in artificial circumstances is attained the problem of appropriate serum therapy will remain beset with difficulties.

Encouraging results have been announced by Rosenow and Nickel [19] for their "streptococcic poliomyelitis serum," obtained by immunising horses with their "pleomorphous streptococcus" said to be derived from human cases of the disease, and injected either intravenously or intramuscularly in quantities ranging from 15 to 75 c.cm., according to age. They claim a much lower mortality-rate and less residual paralysis in 1113 patients treated by this technique than in a series of controls for whom other methods were utilised. I have had no experience of this particular treatment, and most of those who are familiar with the disease bacteriologically do not accept the streptococcus as a causa causans. Nevertheless the method possibly deserves to be tried out further.

No medicinal agent has been proved to exercise a beneficial influence on the course of the disease, although urotropin in large doses is frequently utilised. I have myself employed the drug after a fashion practically identical with that recommended by Hurst,[20] without obtaining any impressive results.

Recently attention has been directed to the procedures adopted and warmly advocated by Bordier.[21] These consist in a combination of spinal radiotherapy with diathermy. As soon as spinal topical diagnosis is established X ray radiation is at once applied; for children under 2 years the dosage is about 200 units R per séance, or 3 units H in a series of three successive séances, measurement being made at the skin level under a filter of 6 mm. of aluminium.

Above the age of 3 the dose may be increased, reaching in the adult 1000 units R or 5 units H in a series of three applications. The rays should penetrate in a direction at right angles to the vertebral laminæ. After one series of treatment some 25 days should elapse ere another is undertaken. The diathermy part of the treatment is intended to favour the nutrition of the tissues of the paralysed limb. It should be utilised from the outset independently of the radiotherapy, and should be carried out daily for about ten minutes. The sinusoidal current is also a useful adjuvant. Favourable reports on this Bordier technique have already been published by Bergamini,[22] Sabatucci,[23] Philips and Galland,[24] and others. Experimental confirmation of its usefulness has been recorded by Kraus.[25] A review of the whole procedure was made a few months ago by Tizier.[26]

Much can be done to mitigate the ultimate sequelæ by absolute rest in bed for at least three weeks and by concentration on the affected muscles. For these the "zero" position must be obtained—i.e., that in which a given muscle is entirely relaxed and its opposing muscle prevented mechanically from exercising its action by appropriate splinting or the use of plaster "shells." Each case requires individual treatment, but the principles are the same in all—no loading or stretching of an atonic muscle is to be allowed. Bearing in mind the spinal site of the lesions the physician must try to maintain the nutrition of the affected groups until such time as recovery takes place from within. Hence there is a place in his therapeutic scheme for the employment of warmth to the limb or limbs, skin friction, warm baths or douches, and gentle massage and movements; the former (warmth) should be carried out from the beginning, the latter after the first week or two are over. Electrical applications of a stimulating kind are less advantageous than is commonly supposed, and in any case are not called for at an early stage.

Later, the same rational physical therapy should be persevered with, active, passive, and resistance movements being practised, usefully in a warm bath, to obviate contracture. At the end of 12 months, speaking generally, further spontaneous improvement is as unlikely as adequate response to a continuation of physiotherapy, and its place should be taken by orthopædic measures, if such are called for.

DAVID ELDER INFIRMARY.—This institution at Govan, which has been erected and endowed from a bequest of £100,000 by the late Mr. Alexander Elder, of Liverpool, has now been formally handed over to the trustees of the Glasgow Western Infirmary.

THE CURE OF GASTRIC AND DUODENAL ULCERS BY INTENSIVE ALKALINE TREATMENT.

BY HUGH MACLEAN, M.D. ABERD., D.SC., F.R.C.P. LOND.,
PROFESSOR OF MEDICINE, UNIVERSITY OF LONDON, ST. THOMAS'S HOSPITAL;

ISAAC JONES, M.D. MELB., M.R.C.P. LOND.,
DEPUTY DIRECTOR, CLINICAL MEDICAL UNIT, ST. THOMAS'S HOSPITAL;
AND
GEOFFREY FILDES, M.B. MANCH., D.M.R.E.,
RADIOLOGIST, ST. THOMAS'S HOSPITAL.

(With Illustrative Plate.)

THE treatment of ulcers of the stomach and duodenum has always been the subject of a great deal of investigation, but until comparatively recently the general opinion held by the profession was that these conditions were more or less incurable by medical means. The natural consequence was that very often patients suffering from these ulcers were subjected to various kinds of surgical operations in an attempt to give relief from the distressing symptoms so often present. No doubt surgery had many great triumphs in this field, but it had also many failures, and on the whole the treatment of these conditions was very difficult and unsatisfactory.

Now, however, we possess quite definite evidence that uncomplicated cases of gastric and duodenal ulcer respond very quickly to medical measures and that by quite simple means we are able to cure these lesions. The principle involved is based on the view that these ulcers are irritated and so prevented from healing by the action of the acid secretion of the stomach. When this factor is removed rapid recovery usually takes place, and the patient's life is changed from one of distress and misery to a condition of comfort and well-being.

Hyperacidity and Gastric Ulceration.

It is common experience that some degree of hyperacidity exists in the patient who is suffering from gastric or duodenal ulceration. This statement has been denied by some observers, but the fact is that the term "hyperacidity" is, perhaps, rather misleading in this connexion. It is quite true that there is often no very definite increase in the *concentration* of hydrochloric acid in these patients. When a test-meal is given and the hydrochloric acid estimated, it may not be higher than normal, though in some cases there is certainly a tendency for a slight increase in amount. The finding of a normal concentration of hydrochloric acid does not necessarily indicate, by any means, that no hyperacidity exists. What really happens in these cases is that acid tends to be secreted *after digestion is completed and after the meal has left the stomach.* There is a secretion of gastric juice when there is no need for it. This tendency for the stomach to go on producing an acid secretion after the needs for gastric secretion are over undoubtedly plays a part in sustaining the chronic condition so often observed in stomach abrasions. By "hyperacidity," then, we mean a tendency for hydrochloric acid to be formed for some time after digestion is completed. This may go on for an hour or two after stomach digestion is over and then cease, or the condition may persist for many hours; indeed, in some patients it may be found that a very considerable amount of hydrochloric acid is present in the resting stomach when the contents are removed before breakfast. In such patients it is obvious that secretion of acid must have gone on for a very long time after the last meal. Now, since there is no food in the stomach to combine with this acid, it seems obvious that this secretion will tend to digest any part of the stomach that has in any way lost its normal resistance to gastric digestion. Whether or not this excessive acid

can per se give rise to an ulcer is not quite certain, but there is little doubt that the condition tends to make an ulcer worse when it is present and to prevent it from healing. If this is admitted—and all the reliable evidence available supports this view—then it is obvious that the best conditions for the healing of an ulcer would be those in which the effect of this excessive secretion of acid is overcome. The best method of treatment would be to stop this secretion, but this is often impossible as long as the ulcer remains, for it acts as a source of irritation. Indeed, the conditions existing in the stomach of a patient suffering from an active ulcer may be regarded as acting in a vicious circle. The ulcer causes irritation which tends to produce an increased secretion of acid; this acid in turn irritates the ulcer, and so matters go on from bad to worse. If we could break this vicious circle either by preventing the injurious action of the acid or by acting directly on the ulcer, the stomach condition in general should improve and the related symptoms should disappear. It is interesting to note that after a successful gastro-enterostomy the contents of the stomach are generally alkaline, or at any rate very much reduced in acidity. On the other hand, when operation affords no relief to the patient, it will be found that the stomach contents still remain highly acid. This observation suggests that the benefit to the patient arising from a successful gastro-enterostomy is in large measure dependent on a change in reaction produced by the mechanical alterations brought about by the operation. How this alteration is brought about is quite easily understood. Presumably the alkaline pancreatic contents pass directly into the stomach via the stoma and so help to neutralise the acid. This assists the ulcerated surface to heal, with the result that the stimulus to increased secretion is gradually overcome. This, in turn, further helps the healing of the ulcer, so that in time it may disappear altogether. The question now arises: Can we by medical means prevent this deleterious action of the acid for a sufficient time to allow the ulcer to heal? There is no doubt whatever as to the answer. In practically all uncomplicated cases of gastric and duodenal ulcer it is quite easy to do this with practically no inconvenience to the patient. This beneficial result is accomplished by the use of intensive alkaline therapy. Sufficient alkali is given to the patient to keep the gastric acid neutralised during a period sufficiently long to enable the ulcer to heal.

The details of this treatment are given below, but it may be said here that the results obtained are as marked as anything known in therapeutics. It is quite extraordinary how these patients respond to this method, but the treatment must be thorough. The usual small doses consisting of a few grains of the ordinary alkalis are of little or no permanent value. Indeed, such treatment may in certain cases do harm rather than good, for insufficient alkali may tend to stimulate acid production instead of decreasing the amount.

The Use of Alkalis in Gastric and Duodenal Ulcers.

Of all the various therapeutic agents used in derangements of the stomach it is generally admitted that, in the great majority of cases, alkalis are by far the most successful in relieving symptoms. Without alkalis there would be an appalling amount of stomach distress. Everybody knows how a teaspoonful or so of such a simple remedy as sodium bicarbonate relieves "heartburn" and other distressing symptoms. Many medical men have from time to time used fairly large doses of alkalis in the treatment of ulcer, and some years ago Sippy in America made many claims for this method. Sippy's directions, however, were rather elaborate and many medical men found difficulty in carrying them out. About five years ago we began to use the plan described here in our treatment of gastric and duodenal ulcer at St. Thomas's Hospital. Our view was that the ulcers should heal if the deleterious action of acid stomach secretion could be entirely prevented for a definite period. The results obtained were entirely satisfactory, but we hesitated to publish our experiences until the method had a thorough trial. We are now satisfied that the results obtained by this method are better than any that have hitherto been described, and that recurrences are extremely rare. Patients who had suffered for periods extending up to 15 years and more often recover entirely from their symptoms in a few weeks; in other patients the period may be longer and may extend to a month or two. It is not necessary to discuss here the various views that have been expressed from time to time as to the manner in which alkalis act in stomach disorders. We are convinced that the action is a direct one, and due simply to neutralisation of the acid secretion. Several observers have given it as their opinion that this action of alkali is an indirect one and that it takes place after absorption, but we are confident that it depends on local action in the stomach.

It might be argued that intensive alkaline treatment would prove injurious because it obviously prevents peptic digestion in the stomach, but in practice this is not found to be the case. After all, the stomach is not an essential organ, and if care is taken that all food that enters it is in the form of a thoroughly soft pultaceous mass, then stomach digestion appears to be unnecessary. Apparently, under such conditions the food is passed on into the intestines, where the most important part of the processes of digestion normally take place. There is really no such condition as "indigestion" in the ordinary physiological sense of the word unless the pancreatic and intestinal secretions are lacking. Digestion of food is easily completed in the absence of the stomach. It is probable, however, that even in the presence of an alkaline stomach fluid, a certain amount of pancreatic digestion sometimes goes on in the stomach. At any rate, experience proves that there is no interference with digestion as a whole when large amounts of alkali are given for long periods. What really usually happens is that any so-called indigestion that may have been present is rapidly relieved as indicated by the disappearance of symptoms.

Other objections to the use of excessive amounts of alkali have been raised from time to time. Bogeys such as "alkalosis" and other equally alarming conditions have been described, but they need not be feared. One of us has carried out an extensive investigation into the possible injurious effects of large doses of alkali on the system. The conclusion arrived at is to the effect that no harmful results whatever are produced except perhaps in patients suffering from advanced chronic interstitial changes in the kidneys. In such patients the end cannot be far distant and the point is not of serious import. As a matter of fact, only very small amounts of the heavy alkalis given are absorbed. They neutralise the acid and pass out in the stools. Only traces are found in the urine. As the result of a large experience we can say with confidence that no fears need be entertained as to the possibility of any pathological symptoms from the large doses of alkali given in the treatment as described here. As already mentioned, the results are extraordinarily good. Patients who have suffered extreme discomfort for many years lose their symptoms very rapidly and soon enjoy quite good health. No operative procedures are necessary in the great majority of patients suffering from uncomplicated gastric or duodenal ulcers, for entirely satisfactory results can be obtained by simple medical means. Of course, when the ulcer has penetrated into one of the adjacent viscera, surgery will be necessary. The same applies when adhesions are formed. Also, in cases of organic obstruction of the pylorus, mechanical means must be used to allow of the passage of the food from the stomach. It is, however, sometimes the case that pyloric obstruction may be largely due to an œdematous swelling of the pyloric orifice, and in such cases alkaline treatment often does much good. In one patient under our care marked symptoms of pyloric obstruction were present for several months,

but an operation was definitely refused. This patient was given alkaline treatment and a modified diet, with the result that the symptoms passed over and she has not vomited for more than a year.

Some Observations on X Ray Appearances.

For some time after beginning this treatment we hesitated to carry it out on patients suffering from large pentrating ulcers as indicated by X rays. Later we found that such ulcers usually responded quite readily to the treatment. Our present plan is to try this treatment on all patients with gastric or duodenal ulcers, no matter how extensive the ulcer may appear from the X ray point of view. Also, we get quite as good results in old-standing conditions as in more recent lesions. If the patient does not respond in a week or two it may be taken for granted either that his symptoms are not due to ulcer, or if an X ray shows an ulcer, that there are adhesions to an adjacent viscus. In such cases it is clear that no medical treatment can be of any avail. It is hoped, however, that intensive alkaline treatment will in the future be used more freely and at an earlier stage, and so help to prevent many of these more or less chronic results of ulceration.

After we had convinced ourselves that intensive alkaline therapy was undoubtedly the most efficacious method for the relief of gastric symptoms, we began to follow the local results of treatment by taking X ray photographs at various intervals during the treatment. In practically every case the ulcer as seen by X rays disappeared in a comparatively short time. Several photographs are given here which prove this quite definitely. No matter what the size of the ulcer, if there are no complications, it disappears in a short time varying from a few weeks to a few months. That it is comparatively uncommon to have ulcer complicated by adhesions to adjacent organs seems to be borne out by the results of our treatment, for among the large number of patients we have treated during the last five years, there have only been a very few in whom surgical intervention was necessary.

The majority of the X ray photographs given here show the results obtained with gastric ulcers, but our experience with duodenal ulcers has been equally satisfactory, though, on the whole, we have the impression that perhaps somewhat longer treatment is necessary in duodenal cases. On the other hand, it is certain that many patients suffering from duodenal ulcers lose their symptoms very rapidly. The reason why we chose chiefly gastric ulcers to represent the results of treatment is merely dependent on the well-known fact that these ulcers show up much better in X ray photographs. Duodenal ulcers are often very obscure from the radiologist's point of view, and not infrequently X rays fail to show such an ulcer though undoubted clinical evidence of its presence may exist. That the photographs in which the ulcers have disappeared really depict healed ulcers is fairly certain, when we consider that not a single patient in our series showed a recurrence on the site of the old ulcer after this had healed. In one patient with a very large penetrating ulcer progress went on in a very satisfactory manner, and after six weeks only a very small ulcer was left. The patient felt quite well, but gave up treatment at this stage and began to drink rather heavily. He appeared at hospital one day after a bout of drinking when an X ray examination revealed the fact that the ulcer had considerably enlarged. The fact that the patient's symptoms entirely disappear as the X ray appearances of the ulcer gets less seems to us to prove that this treatment really cures the ulcer. From five years' experience we are definitely of opinion that the great majority of gastric and duodenal ulcers will readily respond to intensive alkaline treatment on the lines described below.

Details of Alkaline Treatment.

The most important point in treating a patient suffering from ulcer is to give a sufficient amount of alkali to control entirely the acid secretion of the stomach. This can easily be done during the daytime, but may be more difficult during the night. Indeed, it may happen that all the good done in the day may be undone at night unless special precautions are taken. In cases of marked hyperacidity the effect of the last dose of alkali often passes off in a few hours, and if no alkali is taken by night, the patient's stomach may be subjected to the action of acid for several hours. In some patients the tendency to produce acid secretion is so marked that the contents of the stomach may show as much as 0·2 per cent. hydrochloric acid or more within two hours or so after a large dose of alkali. No doubt, in such patients there is a rapid emptying of the stomach with the result that the alkali is passed into the intestine. However this may be, it is difficult to realise that a patient who is taking large doses of alkali at frequent intervals may yet have an acid secretion present in the stomach between the doses. The kind of alkali used does not matter very much, but sodium bicarbonate, when given alone, is unsuitable since it tends to excite a definite flow of acid after its neutralising effect has passed over. On the other hand, sodium bicarbonate is a very soluble diffusible substance and is excellent for quick neutralisation; indeed, it should be remembered in this respect that nature uses this salt to neutralise the hydrochloric acid which passes into the intestine during digestion. When given along with some other alkalis of the alkaline earth group there is no objection whatever to the use of some sodium bicarbonate. Along with this salt we use heavy magnesium carbonate and bismuth oxycarbonate. The proportion of these substances may be varied in relation to the effect on the bowels. Bismuth carbonate tends to cause constipation, whereas magnesium carbonate acts in the opposite direction. If diarrhœa is present the amount of bismuth carbonate can be increased, while, on the other hand, if constipation becomes troublesome, it is well to reduce the bismuth carbonate and to increase the magnesia. We have tried many different mixtures of alkalis, but for the last few years we have used a powder of the following composition:—

Sodium bicarbonate	1 part.
Magnesium carbonate (powd.)	2 parts.
Bismuth oxycarbonate	2 „

This powder when taken in the doses to be described acts as a mild laxative in the majority of patients. As a rule, there is a movement of the bowels two or three times a day to begin with, and then twice a day or so. It is curious how different patients react in different ways for occasionally the powder causes fairly marked diarrhœa, while again it may sometimes give rise to constipation. On the whole, however, it acts well, but any diarrhœa or constipation that may ensue can be easily corrected by an adjustment of the proportions of magnesia and bismuth. Sometimes when constipation is troublesome we keep on with the above powder and give in addition sufficient doses of "magnesia cream" to relieve the bowel condition. After a few days it is quite easy to adjust the alkali to suit the bowels.

For hospital work the large amounts of bismuth required may be found to be too expensive, and to overcome this we have recently used a cheap powder of the following composition; here the amount of bismuth is much smaller.

Bismuth oxycarbonate	1 part.
Sodium bicarbonate	3 parts.
Magnesium carbonate (powd.)	3 „
Creta preparata	3 „

Either of these powders may be used, but if expense is no object perhaps the former is preferable, though there is very little in this. In order that the powder should have its maximum effect, the patient should be fed on liquid diet or so for a week or longer depending on the severity of the condition. When liquid diet combined with alkali is given, the patient quickly loses his symptoms within a day or two, and this is especially true with regard to pain. If, after a few days of treatment the patient still complains of persistent pain, it is probable that the condition is

not an ulcer, or that adhesions to adjacent organs are present. Indeed, this method of treatment is of great value as a means of diagnosis. The exact details of treatment are not important, but a few simple principles must be kept in mind. The most important point is to give sufficient alkali and to see that alkali is available during the night if required. In order to overcome, as far as possible, the possibility of the stomach becoming acid during the night, the patient receives a double dose of the powder immediately before retiring. One or two doses are also left near to his bed and he is warned that if he should wake up with any discomfort he is to take a dose. It generally happens that if acid is formed during the night this causes sufficient discomfort to wake the patient; if he sleeps peacefully throughout the night there is not much need for more alkali, so that by warning the patient as to the necessity for taking the powder whenever he wakes up, the difficulty of preventing acid accumulation during the night may be overcome. Though it is best for the patient to be in bed during the earlier period of the treatment, this is not always necessary, and whether or not complete rest is insisted on must depend on circumstances. We have cured many patients in the out-patient department. After a few weeks of intensive alkaline treatment the amount of the powder given is reduced until it is gradually left off. Its use should, however, be continued for several months, especially in the case of duodenal ulcers. While the exact details of treatment may have to be varied to suit different patients the following general scheme will be found useful in the majority of cases.

First Week.—Patient is kept on a fluid diet consisting of milk or milk and Benger's food. About 3 pints of milk per day are taken. Eight ounces or so of milk are given every two hours. To prevent coagulation in the stomach 10 grains of sodium citrate are added to each glass of milk. A teaspoonful of one of the alkaline powders described is taken every two hours shortly after the milk. The powder is best taken in a little water or milk, but care must be taken to stir the mixture thoroughly immediately before drinking. The powder is practically tasteless, and might be taken in the milk feed, but patients generally prefer to take the milk first and to take the powder afterwards. About six or seven doses of powder are given per day. In addition to this, a double dose is given last thing at night immediately before retiring to rest, and the patient is warned, as already described, to take some extra powder if he wakes up at night, especially if any discomfort is present. Adjustment of the powder or addition of magnesia cream may have to be made if the bowels are disturbed to an excessive degree.

Second Week.—If the patient is complaining of any discomfort and the symptoms still persist at intervals, the procedure for the first week is kept up for a few days longer. If there are no symptoms the powder is reduced to four or five doses a day, the quantity of milk being somewhat reduced also. Two or three eggs are now added to the milk and beaten up. After this a small amount of toast and butter is taken and the diet gradually increased, so that by the end of the week patient is taking, in addition to his milk, a certain amount of toast, butter, eggs, custards, and cream. A dose of powder immediately before retiring is taken as before, and the same care during the night is still necessary. In fact, it is very important that any discomfort arising at night-time during any period of the treatment should be at once checked by a dose of powder.

Third Week.—Powder reduced to three to four doses per day and one at bedtime. Food now gradually increased and should consist largely of eggs, cream, toast and butter, custards, cereal puddings, a little white fish, and a small amount of potatoes.

Fourth, Fifth, and Sixth Weeks.—Milk is given up or very considerably reduced, and powder reduced to three times per day with a dose at bedtime. Food as before with a little pounded chicken added. In the fifth week a little meat may be taken, but only a very small amount. By this time patient is taking a simple nourishing diet and the ulcer should either be healed or well on its way. All the symptoms should have entirely disappeared.

After-treatment.

The powder should be taken two or three times a day for another six weeks. After this, if all goes well, it may be given up during the day if there is an entire absence of symptoms, but a dose should be taken at bedtime for a long time afterwards. Indeed, many patients take this powder as a laxative and it never does any harm.

One most important point is to warn the patient that if any symptoms return he must go back to milk or light diet for a day or two and take the powder four or five times a day. This cuts short an attack which might otnerwise prove troublesome. Patients who have had ulcers are liable to attacks of dyspepsia when they get run down or after an infection such as influenza, but these attacks do not mean that there is a recurrence of the ulcer. This point we have amply proved by X ray investigation in such cases.

Diet.—The diet should be simple, and above all things the food must be thoroughly masticated. Of course it goes without saying that defective teeth should be attended to. The patient should be warned never to eat too large a meal at one time for this tends to cause a recurrence of symptoms. Salads should be avoided, and all fruit and vegetables should be cooked before eating. The patient should be told not to eat anything that could leave an insoluble residue in the stomach. The cellulæ of raw fruit is not digested by the human organism and does much harm by rubbing against the pyloric orifice. Beef-tea and meat extracts of all kinds should be avoided, also heavy foods such as pastry; nuts are better left alone. Indeed, the rules of diet should be based on obvious common-sense principles.

Smoking and Alcohol.—Excessive smoking is a most frequent cause of gastric symptoms, and, if possible, smoking had better be given up altogether, at least for a time. If this is impossible, the minimum amount should be enforced. In our opinion the profession as a whole hardly realises the excessively detrimental action of tobacco on the deranged stomach. Alcohol should be entirely avoided, for it tends to excite the flow of acid which can only be injurious in patients suffering from gastric ulceration.

Other Measures.—The tendency to secrete excessive acid can to some extent be controlled by giving fats or oils between meals. They are of no value unless given on an empty stomach, but if a patient can take such a substance as olive oil, a dessertspoonful two or three times a day shortly before meals may be useful. Cream acts in a somewhat similar way. Various other well-known measures may be used for the control of hyperacidity, but it is unnecessary to discuss them here. In our hands belladonna has been the most useful drug.

Results of Treatment.

A series of X ray photographs (see plate) show the results of this intensive alkaline treatment. In all cases the ulcers are seen to have disappeared in a comparatively short time. The following short notes of the cases described indicate generally the style of case dealt with.

History of Cases.

CASE A.—A police constable, aged 28, was admitted to hospital on Nov. 19th, 1926, complaining of very severe epigastric pain, which had been present in varying degrees of severity for the past six months. There had been very considerable vomiting, which often relieved the pain, generally coming on about one hour after his meals. Pain was also relieved at times by taking small amounts of food. He had been troubled with "indigestion" for some two to three years. One year before admission he had had his right kidney removed for condition of pyonephrosis, due to an aberrant renal artery. Examination showed a very acute tender zone in the upper part of abdomen in costal angle, with the usual rigidity.

This man stated that he was free from pain within a few days after commencing the diet, and he was discharged on Dec. 14th, 1926.

The X ray findings are shown in Fig. 1. In the first photograph (Nov. 19th) a very large penetrating ulcer was seen on the lesser curvature. A second photograph on Dec. 7th showed that the ulcer was still present, but very much smaller. At this time patient was quite well and had no symptoms, so he did not report again until several months later. On April 27th no evidence of ulcer could then be found by X ray examination, the report being "no ulcer now

visible." Since that time he has enjoyed excellent health, and though taking certain dietetic risks has lost no time at work.

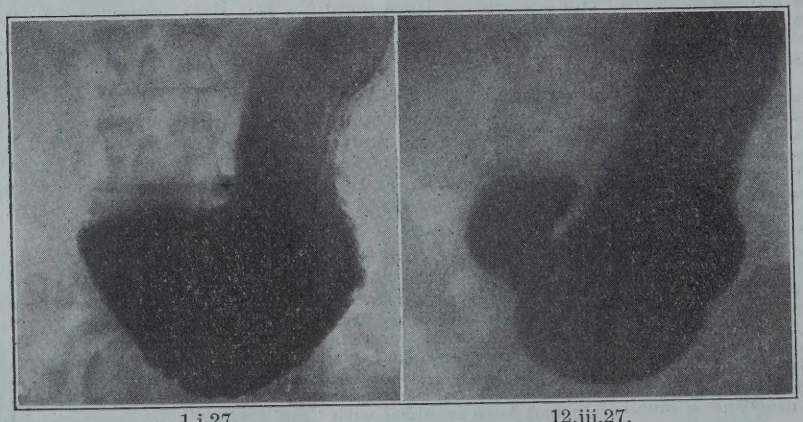
CASE B.—An electrician, aged 38, was admitted on April 27th, 1927, and discharged on June 3rd. He came to hospital with the request that he should be operated upon, as for some six to seven years he had been "a martyr to indigestion," and during the past six months the condition had become so severe that he could not now get relief and could not do his work. He had tried all forms of dietary, but could not control vomiting. He strongly insisted upon operation and resented his being kept in a medical ward, and generally proved a troublesome patient. Symptoms were not allayed for three weeks or so, probably because the patient did not wish to admit that an operation might not prove necessary after all. He then became much more amenable, lost all his symptoms, and in five weeks had put on over a stone in weight.

The radiograms are reproduced in Fig. 2. The first (April 26th) showed a large penetrating ulcer on the lesser curvature which gradually got smaller in size (May 13th) and soon disappeared altogether (June 4th). He is still at work and loses no time, and recent X rays still show negative findings.

CASE C.—The patient, a worker at St. Dunstan's, aged 38, was admitted on July 13th, 1927, and discharged on August 12th. He had lost both eyes during the war through a gunshot wound. For many years had suffered from vague dyspeptic symptoms which had become much more accentuated during the last 12 months or so. Recently had become quite unfitted for his work at St. Dunstan's as the pain was intense. As X ray showed a large gastric ulcer he was admitted for operation to the surgical side. As the man's mental condition was so upset and his general condition so poor he was transferred to the medical side, where alkaline treatment was commenced on July 16th. He was ever impatient and, although symptoms had not completely gone, he preferred to go to his home, where treatment was continued. He has put on a great deal of weight and is free from pain.

The first X ray photograph (Fig. 3) was taken on July 8th and showed a large penetrating ulcer of posterior wall of the lesser curvature. The second photograph, taken on July 29th, showed that the ulcer was much smaller though still

FIG. 10 (Case J).



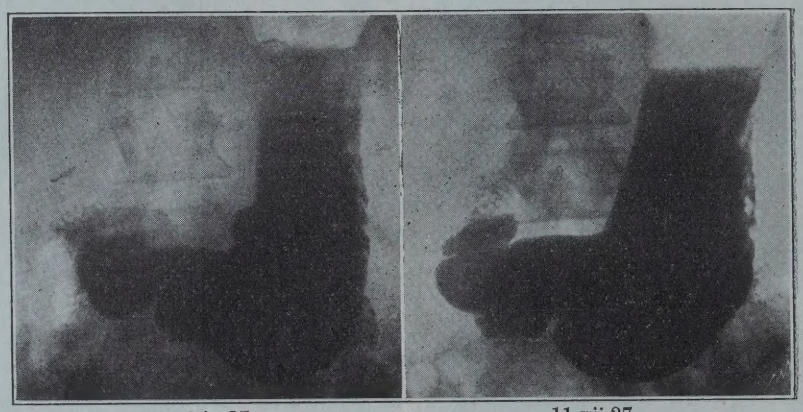
1.i.27. 12.iii.27.

present. On August 28th the X ray report was "no crater now visible." This man is now quite free from gastric symptoms.

CASE D.—A carpenter, aged 45, was admitted on April 8th, 1927, and discharged on the 28th. His symptoms may be summed up by quoting his own statement that he "had suffered from dyspepsia for 12 years or so." He stated that he always had some discomfort in the upper abdomen and at times such discomfort becomes very accentuated. Vomiting had been one of the chief symptoms; it was always worse when the attacks are severe. He had not had any hæmatemesis. Alkaline diet brought relief fairly quickly and the radiographic report changed from "large penetrating lesser curvature ulcer" on April 18th to "small niche in lesser curvature" on May 28th, and "no ulcer now present" on Sept. 22nd. The sequence is seen in Fig. 4. The patient is now quite well.

CASE E.—A railway porter, aged 53, was sent to the out-patient department by his doctor on Feb. 2nd, 1927, with the suggestion that he might be having a slowly leaking gastric ulcer, as the pain had been so very great for some ten days or so. The history went back 20 years, when he was

FIG. 11 (Case K).



9.iv.27. 11.vii.27.

treated by the doctor for "gastric trouble." Since then he had been under the care of doctors on and off, and five years ago condition was labelled a "gastric neurosis." Of late the pain was sometimes so severe that eating and sleeping were almost impossible.

He was a thin, anæmic man, almost cachetic in appearance. His teeth had been extracted many years ago, with the hope of clearing up the condition. Over the right epigastrium there was very acute tenderness on pressure and gross rigidity of both upper recti. The liver dullness was normal and the white blood count was normal. He declined admission to hospital, and his own doctor was advised as to dietary and use of alkalis. He soon got relief and has never looked back; he has put on nearly 3 st. in weight and can do a full 10 hours on duty. His meal-times are very irregular, but he states that he has now no pain or discomfort of any kind.

Here again the X ray findings were very definite, and the photographs (Fig. 5) show that on Feb. 21st there was "a large penetrating ulcer containing gas." On April 21st the report was "crater present, but much reduced in size"; on June 2nd "some irregularity of lesser curvature with small ulcer crater," and on June 30th "now no evidence of gastric ulcer." It is interesting to note that this man was treated quite successfully as an out-patient.

CASE F.—A policeman, aged 45, had had symptoms of indigestion since 1913. He had a gastro-enterostomy in 1917 and gained temporary relief, but most of symptoms returned and gastro-enterostomy opening was enlarged in 1921. No relief was obtained from this and gastro-enterostomy was undone in December, 1922. Again there was temporary improvement, when symptoms returned with unusual severity and accompanied by much loss of weight. Pyloroplasty on July 2nd, 1924, gave very considerable relief, but he still had much abdominal discomfort with nausea, and could not get his weight up to its former level. Gradually he became worse and this year was admitted and put on alkaline treatment. Symptoms within a week were less than they had been for years. He is now quite free from pain, feels fit, and has put on 2 st. in weight. The X ray findings were as follows (see Fig. 6) Sept. 28th, 1927: "Stomach at normal level lying far to left. Whole of antrum is grossly deformed and extremely tender. Emptying is a little slow. The evidence is strongly suggestive of an ulcer in the region of the pylorus and the deforming is probably post-operative." Oct. 20th: "Deformed stomach with apparent fixation of pyloric end. Function normal. No evidence of an ulcer."

CASE G.—A labourer, aged 51, was admitted on July 12th, 1927, and discharged on the 27th. He complained of recurring attacks of dyspepsia for five to six years; for the past eight weeks the symptoms had been much more severe. He was having almost constant pain under the ribs and found that nothing would relieve it. He had evidently tried most remedies. He was obviously suffering a good deal of discomfort in epigastrium, where an area of tenderness could be felt just to right and above umbilicus. There was no blood in stools. The symptoms rapidly disappeared under intensive alkaline treatment and he now makes no complaint.

The radiograms are seen in Fig. 7, the reports being as follows. May 31st, 1927: "Normally placed orthotonic stomach emptying completely in one hour via an extremely deformed cap. Appearance of a duodenal ulcer." July 26th: "Stomach restored to approximately normal function. Duodenal cap shows good outline with only a slight deformity of base."

CASE H.—A police constable, aged 36, was admitted on April 8th, 1927, and discharged on the 25th. He was admitted with a diagnosis of carcinoma of stomach, as symptoms of indigestion associated with loss of weight had been fairly acute. He stated that he had not had a "good stomach" for very many years and any indiscretion in diet would often upset him. On admission he was still well nourished and showed no anæmia. His chief complaint was of a persistent feeling of heaviness in the epigastrium and a complete dislike for food. No tumour could be felt and the stools showed no occult blood. Free HCl was present.

The X ray reports were as follows (see Fig. 8). March 28th, 1927: "Stomach orthotonic and normal in situation with very marked deformity of antrum and a very deformed cap. Emptying time is rather rapid and the appearance is rather suggestive of an early neoplasm." May 26th: "Orthotonic stomach with normal antrum and duodenal cap. Now no evidence of ulcer."

This patient is now quite well.

CASE I.—A married woman, aged 30, was admitted on Oct. 28th, 1927, and discharged on Nov. 19th. She gave a history of very severe upper abdominal pain radiating through to the back. This pain had been present off and on for over three years. In 1925 she was under treatment for some months and again in 1926 for six weeks. During the present year she had never been free from pain and discomfort of some kind. On examination she was well nourished, showing very acute tenderness over the right epigastric region; otherwise nothing gross was detected. From the time she was put on alkaline diet the pain disappeared and she made an uninterrupted recovery. Whereas on Oct. 28th she had a "very large penetrating ulcer of lesser curvature," on Nov. 17th the report was "no ulcer seen and no tenderness" (see Fig. 9). The patient is now in good health and there are no symptoms of dyspepsia. The epigastric tenderness has also disappeared entirely.

CASE J.—The patient was a mechanic, aged 39, and was admitted on Feb. 11th, 1927, being discharged on March 1st. He complained of intermittent attacks of abdominal pain with severe heart-burn and water-brash since 1922. For four months before admission the epigastric pain had been burning and had been accompanied by irregular vomiting after meals. He had lost much sleep on account of the very severe nocturnal pains, which sometimes would keep him awake all the night, and he had lost considerable weight. He was a very spare man, and over the epigastrium (high up) there was almost acute tenderness on pressure with much rigidity. There was definite skin hyperæsthesia. On Jan. 1st radiography showed a large penetrating ulcer midway down the lesser curvature, whilst on March 12th no ulcer was visible (see Fig. 10). He is quite well now and putting on weight.

CASE K.—A cellarman, aged 39, complained of epigastric pain for two years with periods of a certain degree of freedom. The symptoms were accompanied by much vomiting and nausea and he was treated for "gastritis" which was thought to be due to consumption of 3–4 pints of beer a day. Another outstanding symptom was the constant feeling of fullness, associated with much "belching of wind." Incidentally, he was found to have a condition of mitral stenosis with fibrillation. He was put on intensive alkaline treatment with judicious home dietary, with the result that the condition cleared up. He has not since complained of any dyspeptic signs. He was treated throughout in the out-patient department.

Here again the X ray reports showed that a large penetrating ulcer of the lesser curvature had disappeared in about three months (see Fig. 11). The reports on April 9th, 1927, was "appearance of a large penetrating ulcer of lesser curvature, with well-rounded outline." On July 11th it was reported that no ulcer was present.

Some General Considerations.

The use of intensive alkaline treatment often gives good results when all other methods have failed. Generally in post-operative jejunal ulcer the method causes a complete disappearance of the symptoms in a few days. Again, it often happens that patients whose symptoms have not been relieved by operation respond to this treatment. Its use in hæmatemesis is also important, though space forbids the discussion of this aspect at present.

We are firmly convinced that in intensive alkaline treatment we have a simple successful method for dealing with gastric ulceration, and that by its intelligent use practically all uncomplicated ulcers can be cured in a comparatively short time with little or no discomfort or inconvenience to the patient.

THE DIAGNOSIS OF A LIMP,

WITH SPECIAL REFERENCE TO THE HIP-JOINT.*

BY H. A. T. FAIRBANK, D.S.O., M.S. LOND., F.R.C.S. ENG.,

SENIOR ORTHOPÆDIC SURGEON, KING'S COLLEGE HOSPITAL; SURGEON TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

THE diagnosis of the cause of a limp, though often simple enough, is sometimes very difficult. Amongst the causes of a limp are an enormous variety of interesting conditions which may affect any and every tissue and joint not only of the leg, but also of the sacro-iliac and lumbar regions. Some of these conditions are associated with pathological changes which have only been recognised in recent years, and of which the ætiology is still obscure. Even an excellent radiogram may not put an end to the difficulties, yet an early and correct diagnosis may be of supreme importance to the patient. This paper surveys the subject and discusses the affections of the hip-joint in some detail.

Young patients present the greatest difficulties in diagnosis. Their limps vary considerably from time to time and may be intermittent; many children with definite pathological conditions of the hip-joint, for instance, limp only when tired. It is unfortunate that they rarely display their normal gait in the consulting-room. Many curious gaits are met with in children; some of them are hereditary and no adequate cause can be found for them, but these do not, as a rule, deserve the term "limp." Much, however, can often be learned from a patient who limps by watching him walk; a shrewd diagnostic guess is often proved correct by subsequent careful routine examination. The spastic limp of a child with hemiplegia is an example. A thorough routine examination of all the joints of the lower limbs should invariably be made in all children with a limp or a rolling or waddling gait, even though the cause seems obvious. One possible source of error is rickets. A young child, perhaps, is taken to a doctor because he is late in walking, and the doctor quite correctly diagnoses advanced rickets. When the child gradually learns to get on his feet his gait is unsteady and waddling. This is attributed by the doctor to the rickets; but that child has bilateral congenital dislocation of the hips, which may be recognised by another practitioner later, possibly after all signs of rickets have disappeared. Such a mistake, not serious but annoying, might have been avoided by insisting on a routine examination at the first visit, or by a wise repetition of such an examination at a subsequent interview.

A Classification of Limps.

Limps proper can be classified into groups, and I suggest the following as simple and sufficient: (1) the short leg limp; (2) the painful limp;

* A paper read at a meeting of the Norfolk and Norwich Medico-Chirurgical Society.

(3) the stiff limp; (4) the weak leg limp; (5) the hysterical or functional limp. Two or more of these types are often combined.

With a *short leg* the patient either "goes down" on the affected side or walks with the opposite knee bent, rising on that leg at every other step without any rolling of the trunk.

In a *painful limp* it is obvious that the patient is endeavouring to put as little weight as possible on the limb and to relieve it as quickly as possible. He hurries off the bad leg on to the good one, while he may also walk on the toes in order to avoid jarring the tender joint.

In the *stiff limp* one or more joints of the leg fail to move normally, and often there is a certain amount of deformity. Fraser [1] places the short legs with the deformed legs and classifies the limp due to these conditions as "mechanical."

The *weak leg limp* varies considerably according to the extent of the limb affected. The weak leg is usually also a short one. The various types are most commonly seen amongst sufferers from poliomyelitis. In a grossly paralytic leg the limb is flung forward in a loose disjointed manner. If there is foot-drop the knee is often raised abnormally high, so that the toes may clear the ground. If the quadriceps is weak or paralysed the patient may only be able to walk if one hand is placed on the front of the thigh. Lastly, there is the lurching or rolling gait associated with difficulty in sustaining the pelvis on the femur. As the weight is borne on the weak leg the shoulders, and with them the centre of gravity of the body, are thrown towards that side. This is well seen in infantile paralysis, when the glutei are affected, but is present in all conditions which seriously disturb the mechanism of the hip-joint and the action of the glutei muscles.

The *functional or hysterical limp* may simulate any of the above, but tends to suggest a combination of the painful and the stiff types. The three characteristics of this type of limp are exaggeration, variability, and the entire absence of any clinical or radiographic signs of disease. The limp is apt to be grotesque in its exaggeration, particularly if the patient is aware that the doctor's eye is upon her. The gait of hip disease may be imitated. If the foot is held in a deformed position it is almost invariably in the direction of varus. An X ray should always be taken of the joint which is apparently affected. A second or even third examination may be necessary, and is, in fact, advisable, before a definite decision. If the diagnosis of hysteria is correct this will usually be confirmed by the rapid disappearance of the symptoms under treatment, which should always be given in a hospital or institution and should include daily instruction in correct walking.

Differential Diagnosis among the First Four Groups.

Shortening to the extent of half an inch or even more may be present in a child without a limp, and in an adult one inch may be completely hidden. By walking on the toes of the short limb even a greater degree may be masked. If shortening from malunion of fractures of the thigh or leg can be excluded, the child with the short leg is examined as follows. As the child lies on the couch any difference in the size of the two legs is noted and the levels of the great trochanters are compared. If the great trochanter is raised the hip is at fault and will require thorough examination. If the trochanters are level the case is either one of congenital short leg or of infantile paralysis. The poliomyelitic leg may show gross wasting, probably actual paralysis of one or more muscles, and a cold ill-nourished limb, with a knee-jerk either absent or only obtained with difficulty. Sometimes a congenital short limb is smaller than its fellow, and then it may be extremely difficult, or even impossible, to decide between congenital short leg and a mild paralysis.

In the most common congenital type the leg is short and a trifle smaller in girth and nothing more. The shortening may, however, be due to a developmental error in the femur which may even amount to almost complete suppression or may be associated with the presence of masses of cartilage in the ends of the diaphyses, a condition called dyschondroplasia, or Ollier's disease. This usually affects, for the most part at any rate, one side of the body, the arm and leg on the same side being short. It is wise, therefore, to have radiograms of the hip and knee taken in every congenital case to exclude this condition. The arm on the same side in a simple case may be short, however, without any gross changes in the bones. The finding of asymmetry without paralysis in the arms, therefore, may be a useful point in deciding the cause of a shortened leg.

Painful Limp.—The number of conditions which can give rise to a painful limp is legion; they vary from a blister on the heel to spinal caries or sacro-iliac disease. Careful inspection of the gait and history, and the patient's information as to the seat of the pain, supplemented by a careful routine examination, will usually give a correct diagnosis. Supposing, for instance, a child complains of pain in the foot, limps, and is found to have a flattened arch. It is uncommon for a child with uncomplicated flat-foot to complain of pain, though it occasionally happens. Careful inquiry should be made as to the seat of the pain, tenderness should be sought, and X ray films taken. While the condition seen in adolescents usually called Schlatter-Osgood disease of the tibial tubercle, or Schlatter's knee, is well known, it is not generally recognised that a similar chronic painful condition (osteochondritis) may affect the epiphysis of the heel and the tubercle of the navicular bone, points at which, in common with the tibial tubercle, strong tendons are attached. Again in young children, particularly, in my experience, those about the age of 5, a painful and tender swelling occasionally centres on the navicular bone, and raises a suspicion of tuberculosis. A radiogram demonstrates that curious condition called Köhler's disease, where the navicular is represented by a centre which is shrunken and denser than normal. If a series of radiograms be taken this centre is seen in the course of a year or more gradually to assume its normal appearance. X ray examination is essential in all cases where a child complains of pain in one or both feet, whether these are flat or not. Another pathological condition of the foot affects older adolescents and young adults —viz., a spontaneous fracture of one or even two of the metatarsals, the so-called "marching fracture" of the war. Without obvious trauma the patient begins to limp and complains of pain in the foot. A tender thickening is felt in the line of one of the metatarsals, usually the second or third, and a radiogram shows a fusiform thickening of the bone, with or without a definite crack across the shaft.

Other causes of limp are strained or ruptured calf muscles, traumatic affections of the knee-joint associated with slipping of the patella, displacement of a semilunar cartilage, or damage to the articular cartilage (a lesion not so rare as might be supposed), and arthritis of the knee and ankle, which in most young cases will be of tuberculous origin.

There are two main affections of the sacro-iliac joint, the tuberculous and the non-tuberculous. The latter may be a simple strain associated with trauma, pregnancy, or parturition, or the radiogram may reveal definite osteo-arthritic changes in the joint. The limp is a typical painful limp. The lumbar spine is usually tilted towards the opposite side, as if with the object of deflecting the body-weight from the painful joint. There is tenderness over the back of the joint, and pain is referred to it on forced hyperextension of the hip-joint, and on flexion with the knee fully extended; both these movements put a strain on the joint. In tuberculous cases there may be a cold abscess in the buttock, while the radiogram is usually conclusive. In spinal caries of the dorsi-lumbar and lumbar regions there may be spasm or abscess of the psoas, causing fixed flexion of the hip-joint and a limp. When extension of the hip is the only movement of this joint that is impossible, the spine should be examined for stiffness and other signs of caries.

Stiff Leg.—There are two main types of stiff leg limp. In one the whole leg is stiff from a spastic paralysis, and in the other only one joint is restricted in movement. The spastic gait is so common in children that it is hardly necessary to recall the typical jerky limp of a hemiplegic, with the heel well off the

[1] J. Fraser: Brit. Med. Jour., 1921, i., 843.

ground, the whole limb often internally rotated and adducted at the hip, and none of the joints normally flexed or extended as the patient attempts to walk. On examination the hypertonus of all or some of the muscles of the leg, the exaggerated knee-jerk and the extensor plantar response confirm suspicion of an upper segment lesion. In the milder cases, when the leg is often short, help in diagnosis may be given by the condition of the arm on the same side. Even a slight awkwardness in the method of carrying the forearm and hand will be sufficient to determine a hemiplegia. In the second group are included all the affections of the various joints of the leg, traumatic and inflammatory, as well as affections of the muscles, tendon sheaths, &c., which give rise to any stiffness and limitation of motion. Careful inspection of the gait followed by a routine examination, beginning at the toes and carried up to the hip, will usually locate the lesion. The degree and direction of the position in which the hip is fixed are of the greatest importance in determining the severity of the limp, and this is true of the other joints. A hip-joint which is more or less fixed in a slightly abducted and flexed position, but is free from pain, may cause little or no limp in a patient who has learnt to mask his trouble. Nothing, however, can hide the laboured gait of a patient whose hip has become adducted with quite unnecessary apparent shortening. He tires readily and complains of pain in the overworked lumbar muscles and joints in addition to pain about the hip itself. As in all the joints of the leg, it is not so much the limitation of movements per se, even if this amounts to complete fixation, that produces the limping gait and disability, as the undesirable position in which the joint is fixed or the pain which is caused by weight-bearing.

Weak Leg.—For normal gait a certain amount of strong reliable voluntary abduction of the hip-joint is necessary. Anything which interferes with the proper support of the pelvis on one femur as the other foot is raised from the ground will necessitate some abnormal casting over of the centre of gravity of the body towards the affected side at every other stride. For normal gait the hip-joint must supply a stable fulcrum round which the glutei can act; these muscles must be strong enough for their work and not abnormally shortened, and they must have a reasonably good leverage ensured by an approximately normal relation of the trochanter to the head of the femur. In most of the pathological conditions affecting the hip-joint two or more of these desiderata are wanting. For instance, in congenital or pathological dislocation the fulcrum is more or less unstable and displaced upwards towards the origin of the glutei; the leverage is thereby diminished, while the muscles are shortened by the elevation of the trochanter. In the migrated arthritic hip the fulcrum and trochanter are elevated and the lever shortened by erosion of the head and neck of the femur. In a fractured femoral neck the lever is shortened and the trochanter elevated. In infantile paralysis the fulcrum and lever are usually unaffected, but the power of the glutei is diminished or lost.

Differentiation of Limps Due to Affections of the Hip.

A limp is not usually the result of any one factor such as pain, stiffness, or shortening, but of a combination of two or more. Hence it is impossible to classify the affections of the hip-joint strictly under the groups already mentioned. In no joint is the medical man better repaid by systematic examination.

Painless Short Leg with the Trochanter Raised.—There are three possible diagnoses: congenital dislocation, coxa vara, and pathological dislocation (see Table A).

In congenital dislocation the limp has existed since the child began to walk; the patient with coxa vara may give the same history or the limp may have supervened later. In pathological dislocation there has been an illness, perhaps in infancy, with abscess formation and operation and a scar or scars will be found in the region of the hip; this will decide the diagnosis. As a rule the head has been eroded or entirely destroyed and cannot be felt above its normal limit, while the scarring in the region of the joint obscures the emptiness of the acetabulum. In both congenital dislocation and coxa vara abduction is the limited movement; limitation is marked in coxa vara, but is only occasionally a prominent feature of congenital dislocation. In congenital hips the other movements are free, even too free, while in coxa vara internal rotation and sometimes extension are limited. The limitation of movement is usually insufficient to affect the gait; the limp is the result of shortness and weakness. Lordosis is only marked in bilateral cases of congenital dislocation; in coxa vara it is not usually present, except in those severe bilateral cases, the so-called cervical or infantile coxa vara. These closely resemble a double congenital dislocation, particularly in their gait, but are commonly associated with a good deal of pain and disability. The final diagnosis between these two conditions depends upon the position of the head of the femur as determined by manual examination. If it is in the acetabulum, coxa vara must be present. If, on the other hand, the fingers can be abnormally depressed over the front of the joint a dislocation is present. This must be confirmed by feeling the head in the position in which it invariably lies when the dislocation is congenital, namely, in front of the trochanter (not behind, as in traumatic dislocation) and somewhere between this prominence and the anterior superior spine. It can be made more obvious by rolling out the femur. The diagnosis is usually quite simple if only the examination is made in a routine manner. Other interesting but not diagnostic signs include asymmetry of the grooves on the inner side of the thigh in unilateral congenital hips, especially in the younger fat children. Trendelenburg's sign is not diagnostic of congenital hips.

The patient, stripped, stands with her back to the examiner and is told to lift first one foot and then the other from the ground. The position and movements of the gluteal folds are watched. When she stands on the normal leg, raising the other off the ground, the gluteal fold on this side rises slightly with the limb in the normal manner. When, however, she stands on the affected limb the gluteal fold on the sound side falls instead of rising. This is because the glutei on the affected side are unable properly to support the pelvis.

This indicates nothing more than a defect in the osseo-muscular mechanism between the pelvis and the femur. It is present in poliomyelitis when the glutei are affected, in ununited fracture of the femoral neck, in pathological dislocation, and the severer degrees of coxa vara, as well as in congenital dislocations.

TABLE A.—*Affections of Hip in Children or Adolescents.*

Short Leg.—Trochanter raised, long history, no pain, no trauma.
- Cong. dislocation.
- Coxa vara.
- Pathological dislocation.

Painful Hip.—No shortening:—
- (*a*) Recent trauma.
  - Strain of muscle.
  - Traumatic synovitis and arthritis.
  - Acute arthritis.
- (*b*) Remote trauma (or indefinite).
  - (i.) Arthritis present.
    - Tuberculous arthritis.
    - Infective arthritis {Subacute, Chronic.
    - Pseudo-coxalgia.
  - (ii.) No arthritis.
    - Pseudo-coxalgia.
    - Pre-arthritic tubercle.

Shortening. Trochanter raised:—
- (*a*) Recent trauma.
  - Adolescent coxa vara (slipped epiphysis).
  - Fracture of neck.
- (*b*) Remote trauma
  - Adolescent coxa vara.
  - Tuberculous arthritis.

Limp of Uncertain Nature.—Gradual onset, no shortening, no pain. Pseudo-coxalgia.

The Painful Hip.

The first group of cases gives a history of trauma followed by a painful limp, but there is no shortening and no raising of the trochanter.

The possible diagnoses are: (1) strain of a muscle in the region of the joint; (2) traumatic synovitis or arthritis; (3) pseudo-coxalgia; (4) pre-arthritic stage of tuberculosis; (5) tuberculous arthritis; (6) infective arthritis. The hip-joint may be affected by synovitis or mild arthritis after trauma like any other joint.

Pseudo-coxalgia and Pre-arthritic Tuberculous Hip.

Pseudo-coxalgia is only gradually becoming recognised as an entity. These cases used to be lost among the tuberculous hips, but they were observed to recover as true hip disease never does. The affection may be bilateral, but is usually unilateral. A child, more often a boy, of anything from 3 to 10 but usually from 5 to 9 years of age, is brought with a history of some irregularity; this is probably secondary to the alteration in shape of the head.

These changes, destructive and reconstructive, take some two or three years to run their combined course. The ætiology is obscure. Trauma is common and is regarded as causative by some authorities; it has been seen a few times after a traumatic dislocation, a very rare accident in a child, and many times after reduction of a congenital dislocation. My own figures show that pseudo-coxalgia developed in 4 per cent. of the hips reduced. On the whole the evidence is in favour of a mild infection as the cause. While marked limitation of abduction associated with free flexion is typical and, in a healthy looking child, strongly suggestive of pseudo-coxalgia, spasm of all the muscles around the hip may supervene for a period at any time during the course of the disease. This spasm, which fixes the joint, naturally suggests tuberculous arthritis as a possible diagnosis until the X ray examination decides the matter.

TABLE B.—*Diagnostic Table (Hips).*

—	Trauma.	Sex.	Limp.	Pain.	Short.	Age.	Limitation of movement.	Tro-chanter.	General condition.
Adolescent coxa vara.	Definite (repeated).	M.	+	+	+	12–16	Abduction, internal rotation or all.	Raised.	Healthy.
Pseudo-coxalgia.	Often.	M.	+	May be.	Slight.	5–10	Do.	Nil.	Healthy.
Pre-arthritic tuberculosis.	Sometimes.	?	+	+	–	Any age, often young.	Abduction, internal rotation.	Nil.	Tuberculous.
Tuberculous arthritis.	Sometimes.	?	+	+	–	Any age, often young.	All.	Nil.	Tuberculous.

a limp of some months' duration. There may or may not be pain in the region of the hip. The patient is a healthy looking, active child and does not appear tuberculous. The legs are the same length, or, if unequal, the shortening is perhaps half an inch at the most. Abduction of the hip is markedly limited while flexion is surprisingly free. Internal rotation also is generally limited to some extent.

Palpation of the joint may suggest some thickening of the trochanter and neck of the femur, but this is not as a rule definite. The X ray is characteristic and usually diagnostic. Tuberculosis may, very rarely, give rise to a radiogram rather suggestive of pseudo-coxalgia, and if there is any doubt the case should be treated as tuberculous by complete immobilisation until the diagnosis is certain. The changes seen by X ray examination vary with the stage of the disease. The earliest is a slight flattening of the convex centre of the head of the femur, but there is no diminution in the width of the joint space; in fact, flattening of the head may make it appear wider than that on the other side. This is in strong contrast to the diminished joint space in tuberculous cases. Later the head is more flattened, oblong in shape, and abnormally dense. Clear areas next appear, so that the density is very irregular. These areas of rarefaction in the epiphysis increase till the head is broken up into fragments (the stage of fragmentation), while the row of fragments extends horizontally, especially outwards, beyond the normal limits of the head. Improvement then takes place; lime-salts are deposited where they had been removed and the fragments blend so that eventually the head is re-formed. Complete restoration is unfortunately very rare. As a rule the head, though convex again on its upper surface and of normal density, is shallower and more spread out than it should be. It remains, in fact, more or less capped or mushroomed. Shortening develops in the later stages only and never amounts to much. The neck is thickened throughout the course of the disease, and occasionally in a fairly early stage one or more clear areas are seen in it, close to the epiphyseal line. These might at first glance suggest tuberculous foci, but they are clearly outlined by a layer of dense bone, which is only seen in tubercle when healing is well advanced, and then the rest of the X ray picture would be conclusive. The acetabulum usually shows

Pre-arthritic tubercle is a deposition of tubercle, either in the juxta-epiphyseal region of the neck of the femur or beneath the cartilage lining the acetabulum. The deposit is at first extra-articular, but later it reaches the joint cavity and sets up tuberculous arthritis. So long as the disease remains extra-articular abduction, which involves increased intra-articular pressure, is limited; while flexion, which can be accomplished with little or no increase of pressure between the bones, remains comparatively free. Infective arthritis may be acute and suppurative, or chronic and non-suppurative.

If the history of trauma is quite recent the case may be one of strained muscle or synovitis of the joint. With a strain the limitation only affects movement in one direction, while in synovitis all movements are affected, though not necessarily to the same extent. In both cases recovery, after a few days in bed without immobilisation or extension, will confirm the diagnosis. A radiogram should be taken to exclude bony injury and antecedent tubercle which has been aggravated by the trauma. Tubercle does not immediately follow trauma, but takes some weeks or months to give rise to symptoms. Acute arthritis may follow a fall; in fact, in many cases the parents recall some recent trauma to account for the trouble. The severity of the pain and the marked muscular spasm, limiting or entirely preventing movement in all directions, makes the diagnosis of arthritis easy, while fever and leucocytosis place the pyogenic nature of the infection beyond doubt. The difficulty in many cases is to decide whether there is an acute arthritis or an osteomyelitis of the upper end of the femur, or both.

If the trauma is not recent the presence or absence of arthritis must be settled. In arthritis all movements are limited, though not necessarily to an equal extent, and attempts at movement are painful; the joint may be completely fixed by spasm in the position of flexion, abduction, and external rotation. Signs such as tenderness, pain on jarring the hip, wasting, &c., are present in both tuberculous and low-grade pyogenic infections. The appearance of the child and the family history may be helpful, but a radiogram is essential. If there is slight diminution of the joint space and irregularity in the outline of the head, even though this may amount to no more than

a suspicion of fluffiness, the case is almost certainly tuberculous. If the hip appears normal the trouble is probably a subacute or chronic infective arthritis, and the child should be kept in bed with an extension on the leg and a fresh X ray examination made after three or four weeks. If the film is still normal the treatment must be decided by clinical examination. If the movements are not entirely free the treatment must be continued for another month, when a third radiogram is taken. Cases of arthritis in which repeated X ray examinations are negative are not by any means uncommon; they often clear up in a month, but some take longer. The throat, teeth, &c., should be examined. Tonsillectomy may provide a diagnosis as well as a cure. A negative von Pirquet reaction may help.

The age of the patient, his healthy robust condition, and the radiogram distinguish pseudo-coxalgia from tubercle. Daw,[2] of Leeds, has drawn attention to the fact that in pseudo-coxalgia the X ray developments are nearly always in advance of the clinical symptoms, whereas the reverse is true in tuberculosis. A doubtful case of arthritis may, very rarely, develop arthritis of other joints and eventually show all the signs of rheumatoid arthritis or Still's disease. Abduction is the movement chiefly affected in pseudo-coxalgia and pre-arthritic tubercle, while flexion remains surprisingly free. Rotation, particularly internal, is commonly limited in both. Absence of pain is a distinct point in favour of pseudo-coxalgia. The more the pain the greater the probability of tubercle. The robust active boy suffering from pseudo-coxalgia presents a marked contrast to the unhealthy, fragile, tuberculous-looking child, and it is not very common to see a child in the pre-arthritic stage of hip disease. The final decision must rest on the X ray findings, which are usually conclusive.

Slipped Epiphysis and Fracture of the Neck.

The second group comprises painful limps following trauma and accompanied by shortening and elevation of the trochanter. If the trauma is recent the diagnosis lies between adolescent coxa vara (slipped epiphysis) and fracture of the neck of the bone. The latter is very rare in young children and rare in adolescents, and it is excessively unlikely that the impaction will be so firm that walking is possible. X rays decide the matter. The importance of this group of cases lies in the ease with which an early stage of coxa vara may be missed, with disastrous consequences. Partial or complete separation of the capital epiphysis usually occurs in young adolescents, particularly boys. A fall in the football field, perhaps, causes the lad more discomfort than was expected, though he continues the game. Only after a few days of painful limping does he report sick. The degree of limitation of movement varies according to the degree of displacement, but even in the slight cases abduction is often markedly limited. Careful measurement reveals perhaps less than a quarter of an inch of shortening, which might easily be due to natural asymmetry, and might even be overlooked. An X ray picture will show the epiphyseal line on the affected side clearer and wider than that of the other femur. The head looks as if its attachment to the neck were loosened, and this is, in fact, true. Careful comparison between the two sides shows that the head of the affected femur lies at a slightly lower level in relation to the neck, perhaps no more than an eighth of an inch. Normally the head of the adolescent femur appears to project above the neck, while below it does not reach the lowest limit. Unfortunately, these signs of commencing displacement of the head are often overlooked. If the case be unrecognised and the boy allowed to walk the symptoms may disappear, only to reappear in an aggravated form after another fall; from this he may recover, but more slowly, and remain free from trouble till a third fall causes a gross displacement of the head of the femur. On the other hand, the lad may continue to limp about for weeks or even months, with a gradually increasing amount of discomfort. An X ray photograph then shows that the epiphyseal line has been yielding all the time and that the head is markedly displaced from its normal position on the neck.

The second type of case in this group has a history commencing with trauma, but extending over weeks or months, and associated with a painful limp and shortening. Here the diagnosis lies between tubercle and adolescent coxa vara, and only too often the latter is mistaken for the former. There should, however, be no difficulty, even without the assistance of the X rays, which must confirm the diagnosis. The error arises from the fact that when the head of the femur is slipping—even the trauma of walking may be sufficient to increase the displacement—or when the head has been recently shifted to a further degree by a fall, there is set up a spasm of the muscles around the joint, which is absolutely fixed (traumatic arthritis). But the position of the limb is very different in the two affections. In hip disease the thigh is flexed and slightly abducted and externally rotated. In adolescent coxa vara the thigh is not flexed, but lies flat on the couch and is markedly rotated outwards. It is not abducted and may even be adducted. The shortening is considerable in coxa vara and far greater than it would be with tubercle in the time during which the symptoms have been present. In coxa vara the undue prominence of the trochanter is obvious, the patient's age is between 12 and 17, and there is nothing about his general appearance to suggest tubercle.

Pseudo-coxalgia during a period of spasm is the only other possible diagnosis, but here the shortening is slight—not more than half an inch after many months, with or without treatment—and considering the age at which this affection occurs it cannot be confused with adolescent coxa vara. The absence of pain would be strongly in favour of pseudo-coxalgia, and a radiogram will decide. The importance of age in the differential diagnosis of the various hip affections was aptly defined by Mr. Harry Platt during a discussion on coxitis last year. He said:—

> Broadly speaking, a persistent hip lesion in a child under 5 is likely to be tuberculous arthritis; between the ages of 5 and 10 pseudo-coxalgia is at least as common as tuberculous arthritis, while in the second decade tuberculous hip disease becomes a comparatively rare lesion, the characteristic affection at this age-period being traumatic coxa vara (i.e., adolescent coxa vara); at all ages a transitory arthritis due presumably to trauma or infection might be seen.[3]

Finally, we have the group with a long history of an indefinite limp which came on gradually without shortening or pain. Trauma may or may not be mentioned. If the child is of suitable age the diagnosis is in all probability pseudo-coxalgia. No attempt has been made here to deal with all the affections, traumatic, infective, and neoplastic, to which the hip is prone.

PROCEEDS OF A HOSPITAL BALL.—The ball which took place at Covent Garden Theatre recently in aid of the Infants Hospital, Westminster, produced £5000, which has just been paid over.

THE LATE DR. J. G. MCCANDLISH.—The death took place on Dec. 7th, at Blackpool, at the age of 59, of Dr. John Gordon McCandlish, while he was on a holiday at Leeds. Born at Leeds in 1868 he was educated at the Leeds Grammar School, at the Yorkshire College, and at Edinburgh. After qualifying as L.R.C.P. Edin. in 1890 he became house surgeon at the Leeds General Infirmary, and in the following year started practice for himself in the town. He was for a time a member of the Leeds Board of Guardians and a member of the city council. In 1905, owing to the state of his health, he withdrew altogether from public work in Leeds, and went to live in retirement at Blackpool. He leaves a widow, one son, and two daughters.

ON A PARASITIC FŒTUS.

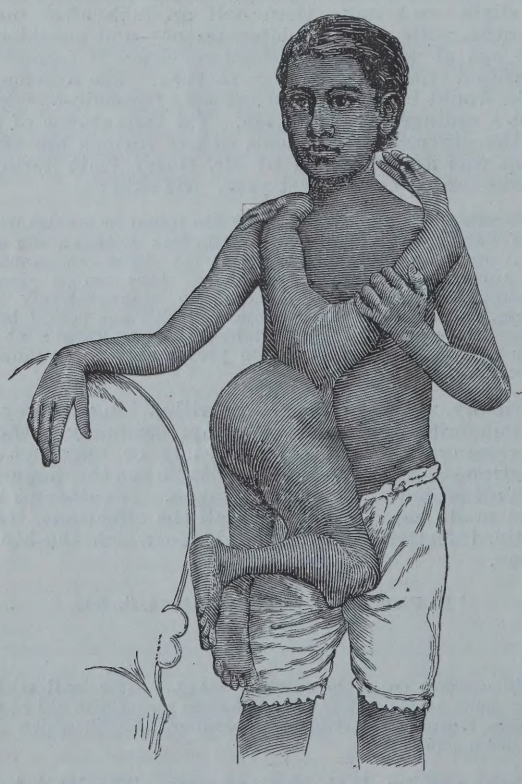
By Sir JOHN BLAND-SUTTON, Bart., F.R.C.S. Eng.,
CONSULTING SURGEON TO THE MIDDLESEX HOSPITAL.

A FEW months ago Capt. D. D. Kapur, M.B., B.S., of Gujarkhana, Rawalpindi, at the suggestion of Capt. S. N. Hayes, I.M.S., sent me an account of a parasitic fœtus which he had successfully removed from a native boy aged 26 days. I advised him to supply notes of the case to the *Indian Medical Gazette*, and when they were published to send me a copy and I would endeavour to bring the facts under the notice of British surgeons. This advice he followed.

A male child, Karamat Hussain, was born Jan. 27th, 1927, in a village near Gujarkhana; attached to the boy was a parasitic fœtus, which in conformation, position, and mode of attachment to the autosite, was the counterpart of the Hindu lad Laloo, which the late S. G. Shattock and I described to the Pathological Society, London, in 1888 (Fig. 1).

In Kapur's case the parasite consisted of chest and abdomen, upper and lower limbs. Each hand had two thick fingers and each foot five toes. The chest was without heart or lungs. It had complete male reproductive organs and the scrotum contained two testicles. The anus was indicated by a dimple. "The parasite,

FIG. 1.



Laloo, a Hindu lad, with his parasitic brother. ("Tumours.")

which had feelings for cold and heat and pin-pricks," was joined to the autosite at the lower part of the sternum and upper part of the abdominal wall. The parasite voided urine independently of his brother, and usually over him, causing much discomfort day and night. A month after birth the parasite was growing rapidly, "and the parents were afraid that the life of the child would become very troublesome." On this account they sought the aid of surgery.

An incision was made around the pedicle joining the parasite to its brother. The abdominal cavity of each freely communicated. The intestines of the parasite had a separate mesentery which adhered to

FIG. 2.

James Poro (born at Genoa, 1686).

the posterior wall of the abdomen. The intestines were thin and had a narrow lumen. Below they joined the lower part of the intestine of the autosite. Large blood-vessels and nerves passed from the autosite to the lower limbs of the parasite; the vessels were ligatured and cut short. There was one kidney in the parasite. The whole intestine of the parasite and the mesentery were transferred into the abdominal cavity of the autosite. The incision was closed in the usual way. The autosite weighed 7 lb., the parasite 1 lb. The child recovered and five months later the report ran: The child has developed normally, is fit and well, and growing nicely.

The facts of this case are worth reporting not only from its intrinsic interest, but also for the stimulus it gives to surgeons to separate conjoined twins and spare the autosite not only a dreadful life of bondage, but the disgust and ignominy of being exhibited for gain in public shows.

As in the case of Laloo, at birth, the parasite had its arms around his brother's neck and was delivered without difficulty. In Kapur's case the mother was a multipara, aged 35, and the conjoined twins were born easily.

It is now accepted that conjoined twins are the product of a single ovum. Occasionally both twins develop equally. It happens, not infrequently, that one of the twins is complete, but its companion is an "indigested and deformed lump." The parasite may be a headless trunk on an otherwise well-formed individual. A very rare variety is a deformed head on a limbless trunk. Capitate teratomas are rare. Dr. Dan McKenzie found in a second-hand bookshop an engraving representing a teratoma of this kind, attached near the navel of a handsome adult, born at Genoa, 1686 (Fig. 2). If any reader can supply the history of the said Poro, the writer of this note will be his debtor.

FURTHER OBSERVATIONS ON THE EFFECTS OF PLASMOCHIN AND "PLASMOCHIN-COMPOUND"

ON THE GAMETOCYTES OF BENIGN TERTIAN AND SUBTERTIAN MALARIA.

By P. H. MANSON-BAHR, D.S.O., M.D. Camb., F.R.C.P. Lond.,

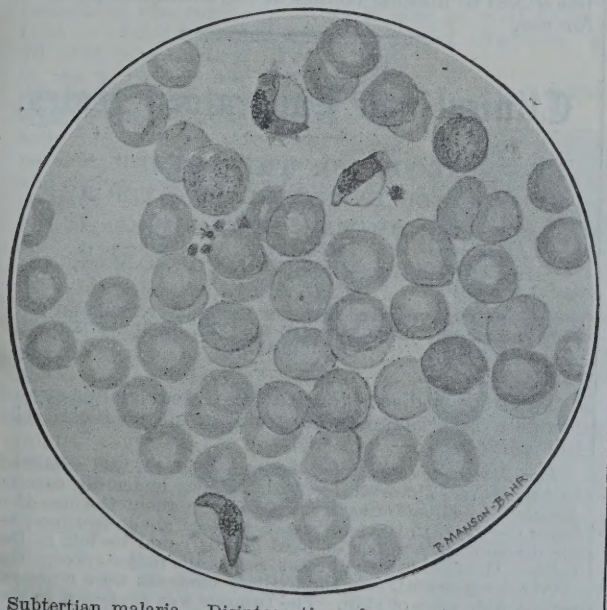
PHYSICIAN, HOSPITAL FOR TROPICAL DISEASES; LECTURER AT THE LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE; MEMBER, COLONIAL MEDICAL RESEARCH COMMITTEE.

THOUGH pure plasmochin in therapeutic doses has a lethal action on the schizonts of benign tertian malaria, it has a more striking effect upon the gametocytes both of this species and of the subtertian.[1] In some individuals pure plasmochin produces a toxic effect which manifests itself in cyanosis, but this toxicity seems to be entirely eliminated by the mechanical combination of plasmochin with small quantities of quinine sulphate in the form now known as "plasmochin-compound." The latter, as this paper will show, has a direct action upon the gametocytes every whit as strong as that of plasmochin by itself.

Action of Quinine upon the Gametocytes.

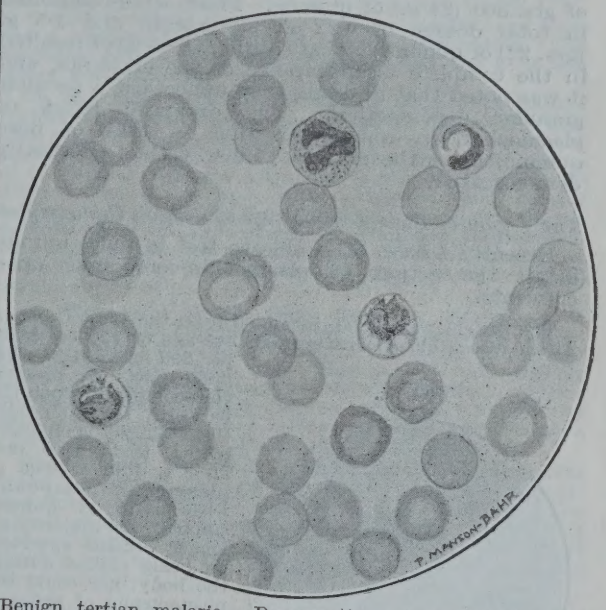
It is well known that quinine in therapeutic or even in heroic doses appears to have no direct influence upon the crescent of the subtertian parasite and is less efficacious in destroying the benign tertian gametocytes than it is in extirpating the younger schizonts of this parasite. In the compilation of this paper I have looked up my records of the past eight years on the effect of prolonged quinine administration upon the crescents of subtertian cases. There are 17 in which exact observations were made and in which the crescents were sufficiently numerous (from 8-132 to every 200 leucocytes) to warrant the drawing of any inferences. Upon full therapeutic doses of grs. 30 (2 g.) of quinine hydrochloride daily the average length of time crescents remained visible in the blood stream was 13 days, and the average number of grains of quinine hydrochloride administered was 390 (26 g.). The extremes in heavily infected cases were 28 days (grs. 840 or 56 g. quinine, in addition grs. 10 intravenously and grs. 30 intramuscularly), and 26 days (grs. 780 or 52 g., quinine, with grs. 10 intramuscularly and two injections of 0·3 g. novarsenobenzol). Other cases received, in addition to intramuscular quinine, injections of N.A.B. and two tablets of stovarsol daily without any ascertainable effects. In two instances there are records of the appearance of crescents in the peripheral blood of patients originally admitted with a heavy infection of subtertian rings while on full doses of quinine. In one crescents were seen after grs. 540 (36 g.) of oral quinine hydrochloride and grs. 14 intramuscularly, and in the other after grs. 420 (28 g.). It is thus seen that, whatever the mechanism underlying the production of crescents may be, so far from being destroyed by the action of quinine, the tendency is for the crescent—the more durable form of the subtertian parasite—to make its appearance in the circulation in the period during which quinine is exerting its maximum effect upon the younger schizonts. The inference which may be drawn from this observation is that quinine is less toxic for the young gametocyte than for other stages of the parasite.

FIG. 1.



Subtertian malaria. Disintegration of crescents (gametocytes) after taking 0·08 g. plasmochin and 1·0 g. quinine sulphate. Thirty-six hours from commencement of treatment. (Camera lucida.)

FIG. 2.



Benign tertian malaria. Degeneration of gametocytes after taking 0·06 g. plasmochin and 0·75 g. quinine sulphate. Twenty-four hours after commencement of treatment. (Camera lucida.)

The Action of Pure Plasmochin upon Gametocytes.

In four cases of subtertian malaria it has been possible to observe the effect of pure plasmochin upon crescents. The drug was given in cachet form in doses varying from 0·06 to 0·12 g. daily. In every instance the crescents disappeared from the circulation two to three days before the ring forms. The average number of days in which they were visible was four, and the average amount of plasmochin necessary for their destruction 0·3 g. No opportunity occurred at that time of making minute observations on the degeneration of the crescents before their disappearance. In six cases of benign tertian malaria in which special attention was paid to the gametocytes, the action of plasmochin upon these forms was equally striking, and the dose of plasmochin was the same.

[1] Proc. Roy. Soc. Med., 1927, xx., 919.

In June, 1927, in a heavy case of subtertian malaria with numerous ring forms—the patient taking full therapeutic doses of grs. 30 (2 g.) of quinine daily, it was noted that crescents appeared in the blood after the fourth day of treatment. Full doses of quinine were continued for the next eight days, at the end of which period they were even more numerous than before. The patient had then received a total of grs. 360 (24 g.) of quinine. Plasmochin-compound in total dosage of 0·12 g. plasmochin and 1·5 g. (grs. 22) of quinine sulphate during three days resulted in the complete disappearance of the crescents, and it was noted that in dying they underwent a peculiar granular degeneration. The dramatic effect of plasmochin, in contradistinction to that of pure quinine, upon the gametocytes was thus effectually demonstrated.

The Action of Plasmochin-compound upon Gametocytes.

Recently I have been able to test in more minute detail the action of plasmochin-compound upon crescents.

The patient was a man invalided from the West Coast of Africa whose blood contained an average of 150 crescents per 200 leucocytes. The first effects of plasmochin-compound upon the parasites was to render them almost completely inert; that is to say, after a dose of 0·03 g. plasmochin-compound with 0·375 g. quinine sulphate the majority no longer became spherical on being chilled outside the body, nor could the phenomenon of exflagellation be produced in any of them. Within 36 hours of the commencement of treatment (0·08 g. plasmochin and 1·0 g. of quinine) the crescents had assumed the bizarre and distorted shapes seen in Fig. 1. The protoplasm of the parasites had undergone a granular degeneration, while the chromatin was broken up into small clumps. Within 24 hours of the time of making this observation the disintegration of the crescents had been completed. Three further cases of subtertian malaria were treated with 0·08 g. plasmochin plus 1·0 g. of quinine with similar results.

FIG. 3.

Subtertian malaria. Appearance of crescent (gametocyte) in control case after taking 6 g. of quinine. (Camera lucida.)

In benign tertian malaria observations have been made with plasmochin-compound in 11 cases. In all of them the action of the drug was almost uniform, but less striking than in the case of the subtertian crescent. The drug appears to have an equally toxic effect upon sporonts as on the schizonts of the parasite. After treatment for 24 hours with 0·06 g. plasmochin and 0·75 g. quinine the degeneration of the parasite had commenced (Fig. 2). Again the same breaking up of the protoplasm and separation of the pigment and chromatin was observed, while the outline of the host cell can be distinguished as a hazy outline. After an average dose of 0·12 g. plasmochin plus 1·5 g. quinine the destruction of the benign tertian parasites was complete.

The therapeutic effects of plasmochin-compound in both forms of malaria has thus been conclusively demonstrated. I have been unable to observe the effects of this drug in quartan malaria.

Clinical Results.

The clinical results of plasmochin-compound treatment in my experience have been good—being a general improvement of the patient, rapid diminution in the size of the spleen (as formerly noted with pure plasmochin), and a complete absence of any toxic effects. Occasionally complaints have been made that the drug affects the digestion, but this appears to be but transient.

In order to produce a clinical cure with plasmochin-compound it appears to be necessary to continue in full therapeutic doses (0·06 g. plasmochin plus 0·75 g. quinine daily) for three full courses of one week each with intervals of five to seven days in between in order to eliminate the drug from the body.

It is too early yet to state whether plasmochin-compound effects a permanent cure in both these forms of malaria, but so far, during the past six months, no relapses have been reported by any of the patients whose cases are recorded in this paper. Children up to 7 years of age seem to tolerate the drug well in doses of 0·2 g. plasmochin plus 0·25 g. quinine. The youngest patient of 3½ years was treated with half the latter dose.

Conclusions.

Plasmochin-compound exerts a selective action upon the gametocytes of subtertian and benign tertian malaria. Even in small therapeutic doses its action upon the parasite is much more rapid and striking than that of quinine uncombined with plasmochin. The drug has the additional advantage of being tasteless, and is extremely well tolerated. The clinical results so far observed have been very satisfactory. The effect of any drug upon the crescent, which is admittedly the most resistant form of the human malaria parasite, can be taken as an index of its efficacy. In this respect it has been shown, by the facts stated above, that plasmochin in combination with small doses of quinine appears to have a much stronger parasitotropic action than either drug administered singly.

My best thanks are due to Dr. L. M. Maybury and Dr. S. K. Montgomery, my house physicians, for the care they have taken in keeping accurate records, and to Mr. F. W. Foster and Mr. R. McKay for the trouble they have expended in taking daily specimens of blood and in making counts of the contained parasites for me.

Clinical and Laboratory Notes.

SARCOMA OF THE BREAST FOLLOWED TWENTY YEARS LATER BY ABDOMINAL CARCINOMA.

BY ANDREW FULLERTON, C.B., C.M.G., M.Ch. Belf.,
PROFESSOR OF SURGERY, QUEEN'S UNIVERSITY, BELFAST; PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS IN IRELAND.

THE recent discussion [1] at the Medical Society of London on breast cancer prompts me to record the following case :—

Past History.—A married woman, aged 42, was admitted to the Royal Victoria Hospital, Belfast, under my care in January, 1906, suffering from a tumour about the size of a horse chestnut in the left breast, noticed about two months previously. A number of hard glands could be felt in the axilla. On Jan. 9th the breast, pectoralis major (except the clavicular portion), and the axillary contents were removed with a wide area of skin. The tumour was examined in the pathological department of Queen's College and the following report was given, "mixed sarcoma and carcinoma—highly malignant."

Five years later Sampson Handley's lymphangioplasty was performed for œdema of the upper arm with a satisfactory result. In 1924 a second lymphangioplasty was performed for œdema of the forearm, but the result was not so satisfactory. There were no signs of recurrence at this date.

Recent History.—In May, 1926, that is, 20 years and four months after the first operation, she was again admitted with the history that three months before she had noticed a small lump in her abdomen. On examination a number of ill-defined swellings could be felt in the abdominal cavity

[1] See THE LANCET, 1927, ii., 1181.

and free fluid was demonstrated. On May 28th a small opening was made into the abdominal cavity for diagnostic purposes. Innumerable firm papillomatous growths, of varying sizes, were found scattered all over the peritoneum from the diaphragm to the pelvis. The abdomen contained a large amount of clear fluid. A portion of growth was removed from the omentum for microscopical examination. We were fortunate in being able to find the paraffin block of the original tumour carefully numbered and labelled. Fresh sections of the tumour of 1906 and sections of the 1926 tumour were examined and compared by Prof. W. St. C. Symmers, who reported as follows:—"Breast tumour of 1906: This is a sarcoma, large round cells predominate in parts, smaller cells elsewhere. Peritoneal growth of 1926: This is a papillomatous mass, densely overrun with glandular-like masses of columnar epithelium. I suggest that this is one of many implantation metastases originating from papilloma of the surface of the ovary."

The patient had lead treatment, following, as closely as possible, the technique recommended by Blair Bell, but succumbed a few months after leaving hospital. The case is of interest in that the patient apparently was cured of one form of malignant disease to die, 20 years later, of another.

A CASE OF CORONARY OCCLUSION FOLLOWING PARTURITION.

By H. Wallace Jones, M.Sc., M.D. Liverp., M.R.C.P. Lond.,
SENIOR HON. ASSISTANT PHYSICIAN, LIVERPOOL ROYAL INFIRMARY;
AND
C. Allan Birch, M.B. Liverp., M.R.C.S. Eng.,
LATE HOUSE SURGEON, LIVERPOOL MATERNITY HOSPITAL.

THE clinical syndrome of sudden occlusion of a branch of the coronary artery is now so well known that a brief summary of its chief features is all that is necessary. The patient is, as a rule, seized with severe retrosternal or præcordial pain which may radiate down the arms or up into the neck. This pain may be agonising in severity and, unlike ordinary angina pectoris, is more or less continuous, frequently lasting days or even weeks and necessitating large doses of morphia for its relief. This is generally accompanied by signs of pericardial friction, rise of temperature, rapid pulse, marked dyspnœa and cyanosis, leucocytosis, moist sounds at the bases of the lungs, and often general cardiac failure of the "congestive type." Death may occur immediately or the patient may recover for a period varying from a few hours to several years. More than half of the cases fall into the group in which temporary recovery occurs.

The case we wish to describe was that of a multipara, aged 26 years, suffering from mitral stenosis and a slight aortic leak with a fairly well-compensated lesion. She had no evidence of arteriosclerosis, her blood pressure was normal, and her Wassermann reaction was negative. This was her second pregnancy and she was kept under observation during the greater part of its duration. She began to be somewhat distressed at thirty-three weeks, but it was decided to allow her to go another two or three weeks before inducing labour. A week later, however — i.e., at thirty-four weeks — she commenced labour normally and a living male child, weighing 4 lb. 8 oz., was delivered. The total duration of labour was three hours, the second stage being of five minutes' duration.

The puerperium was normal until the eleventh day when the patient was suddenly seized with severe pain behind the sternum. The pain was continuous and remained localised to the lower end of the sternum and was accompanied by some localised tenderness with a marked sense of constriction in the lower part of the chest. The pulse-rate was rapid (108) and the temperature rose to 100·4° F. There were also a few moist sounds at the bases of the lungs, with some dyspnœa and cyanosis. The next day there was a further rise of temperature to 101·4° F., the moist sounds in the chest were more marked, and there was a considerable amount of frothy expectoration. The dyspnœa and cyanosis were increased and the liver and spleen were palpable.

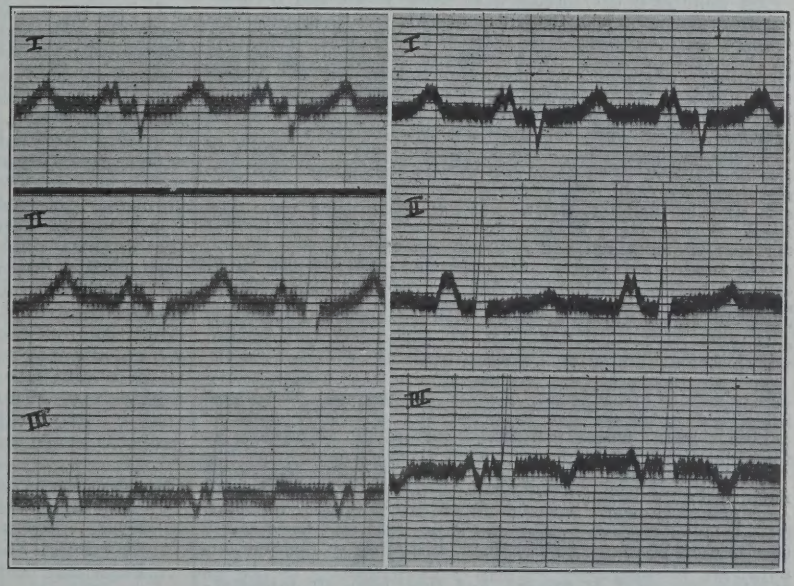
On the third day of the attack definite pericardial friction was noted slightly to the left of the middle line. The pain began to be less intense, though the dyspnœa again became more marked and for the first time œdema of the ankles appeared. On the fourth day her general distress was so marked, with orthopnœa and general œdema, that death was thought to be impending. On the next day, however, she commenced to improve, the temperature began to fall, the pericardial rub disappeared, while on the sixth day for the first time the temperature remained normal for 24 hours.

A blood count at this stage showed a leucocytosis of 20,000 per c.mm. From this time she improved steadily; she was in bed for a total period of six weeks, but is now able to go about quite well. Her heart is now slightly larger than before the attack but the valvular lesion appears unaltered, though dyspnœa is now more easily induced by effort than formerly. She has remained entirely free from cardiac pain since the attack.

We obtained electrocardiographic records three weeks before the attack (i.e., one week before labour commenced) and eight weeks after the attack (see Figs. 1 and 2). The second record shows inversion of the "T" wave in lead III. where this had been upright in the first record and also it shows a very small "T" wave in lead II. where previously there had been a large "T" wave.

This case we believe is of special interest from the following points of view: 1. Was this a case of primary coronary thrombosis occurring at an early age or was it a case of coronary embolism? 2. The accident occurred at the eleventh day, a period at which the tendency for the blood to clot after parturition reaches its maximum. 3. It is the only case which we can find in the literature where this accident has occurred after parturition and has been followed by recovery. 4. An electrocardiogram was taken three weeks before and eight weeks after the attack.

FIG. 1. FIG. 2.



Three weeks before attack of coronary occlusion. Eight weeks after attack.

A CASE OF SARCOMA OF THE CHEEK

TREATED BY OPERATION AND INJECTIONS OF COLLOIDAL LEAD.

By J. Bagot Oldham, M.B. Liverp., F.R.C.S. Eng.,
HON. ASSISTANT SURGEON, DAVID LEWIS NORTHERN HOSPITAL, LIVERPOOL.

In a recent article (The Lancet, 1927, ii., 703) Mr. Norman Patterson suggested a new method for dealing with certain neoplasms of the face. As I had employed the same principle myself over a year before, Mr. Patterson's article stimulated me to follow up my case. The record may be of interest.

The patient, aged 50, came to the out-patient department of the David Lewis Northern Hospital at the end of July, 1926. He complained of a lump on the inner side of his right cheek, first noticed some nine weeks before. On examination I found a round growth, three-quarters of an inch in diameter, on the inner side of the cheek. This lump, which was not hard but elastic in consistence, was opposite the bicuspid teeth and was beginning to ulcerate. The skin of the cheek could be moved over the surface of the tumour. The right cervical glands were enlarged but mobile; the left cervical glands were impalpable. There was no sign of any lesion in the chest or elsewhere.

Under local anæsthesia, a section was taken from the tumour, the incision being afterwards cauterised with carbolic acid. The section showed a mixed-celled sarcoma.

The patient was admitted to hospital and I operated on him on August 14th, 1926. I had previously experienced the difficulty that Mr. Patterson mentions of dealing efficiently with neoplasms in this situation without seriously disfiguring the face. I therefore employed the incision that Moure suggested for removal of the upper jaw, starting at the outer side of the orbit, running along the infra-orbital margin to the side of the nose, down the outer side of the nose, round the ala nasi, and then down the centre of the upper lip. I only made the incision skin deep and did not prolong it into the red margin of the lip. I then dissected back the skin-flap off the underlying tissues. The tumour was now removed, together with a margin of surrounding healthy tissue, by means of the diathermy. The hole which has been made in the cheek by the removal of the tumour was reduced in size by means of a few tension sutures. The deep surface of the skin-flap was lightly diathermised and then sutured back into place.

All went well till August 31st when there was a smart secondary hæmorrhage which compelled me to ligature the external carotid artery and its facial branch. The right side of the mouth drooped considerably as the facial nerve and the muscles of the face had been removed, in part, in excising the tumour. The patient left the hospital on Sept. 9th. The pathological report on the tumour was "mixed-celled sarcoma, nodule showed calcareous mass in part."

For some reason or other the patient did not return to the hospital till Oct. 21st, and it was then found that the glands in the right side of the neck had greatly enlarged in size since he had left the hospital and that they were now fixed. At operation on Oct. 23rd I removed the glands, and the scar tissue which had followed the tying of the artery, as thoroughly as I could. Convalescence was uninterrupted and the patient left the hospital on Nov. 11th. During his stay in hospital—on Oct. 28th and on Nov. 11th—I gave the man two intravenous injections of 15 c.cm. of 5 per cent. colloidal lead (as prepared by the Liverpool Medical Research Organisation, under the direction of Prof. Blair Bell). After his discharge my colleague, Dr. L. Cunningham, continued to treat him, as an out-patient, with lead injections until he had received, in all, 100 c.cm. of colloidal lead. These injections were given at weekly or fortnightly intervals; 5 c.cm. were given at each injection.

The first report on the glands was that they showed nothing but inflammatory reaction, but on further section one gland showed quite definite sarcomatous invasion. Glandular metastasis in sarcoma is unusual, so I have asked the opinion of many pathologists, including so eminent an authority on neoplasms as Dr. J. C. Bloodgood, of Johns Hopkins Hospital, Baltimore, and they have all unhesitatingly confirmed the diagnosis of sarcoma.

On Dec. 11th, 1926, the man came to see me; the right side of his face was swollen up. I found a brawny red œdematous area on the outer side of the right cheek just over the place where the tumour had been. I opened the swelling and a little pus came out. A small piece was taken and sectioned but showed no evidence of sarcoma. The swelling rapidly subsided.

The man is to-day in perfect health. The cheek is soft and supple and there is no sign whatever of any local recurrence. It is now nearly impossible to see the original incision. The right side of the neck, which at the time of the operation on the glands was swollen and indurated, is soft and normal; the scar is mobile. There is now no drooping of the right side of the mouth, though the movements of the right side of the face are somewhat defective. There is no clinical or X ray evidence of any metastasis in the chest. The man has put on weight.

This case seems to me to be of interest for three reasons. First, the principle employed in making the flap is the same as is used by Mr. Patterson. The flap used by him has the advantage of allowing the facial artery to be tied; that employed in my case would, I think, be a better one for tumours situated in the upper part of the cheek. The second feature of interest is that a case of undoubted sarcoma, and one which had already invaded the glands, should be alive and well 18 months later. Lastly, the case is an example of glandular metastasis in sarcoma.

Reviews and Notices of Books.

Outlines of Pathology.

In its Historical, Philosophical, and Scientific Foundations. By H. Oertel, Strathcona Professor of Pathology in McGill University, Montreal. Montreal: Renouf Publishing Co. 1927. With 132 coloured and plain figures. Pp. 479. 50*s*.

Pathology is a science of itself and unless it develops its own individuality it will never cease to be the 'tweeny of clinical medicine. There are a good many signs that some such view is commoner than it was 20 or 30 years ago; at Cambridge, for example, under Prof. H. R. Dean, pathology has become one of the subjects for Part II. of the Natural Science Tripos, and not long ago Dr. Powell White wrote a book to illustrate the biological significance of his science. Prof. Oertel holds that it is the business of pathology to work out a causal mechanistic explanation of the morphological changes which accompany disease. Whether they look on Prof. Oertel as a prophet or a heretic, everyone with a serious interest in pathology ought to read his book, in which they will find the topics familiarly grouped under "general pathology" treated in an atmosphere of history and philosophy which they have probably not met with before in this connexion. We are bound to agree with his contention that a subject ought to be studied in its historical relationships and that we ought to be more careful in our thinking, not confusing (as we often do) interpretations with explanations and talking rather wildly about causation. But careful thinking does not necessarily mean a return to the mechanistic biology of last century, and to ban any teleological outlook as unscientific is in our view essentially unsound and pedagogically disastrous. If biologists had known more about pathology—about the reactions of the body to unfavourable conditions which pass through their cycles in a time which enables us to see the whole process—more of them would have a conviction that the live world is purposive. It has been wisely said that a theory is true if it is fruitful; by that test teleological interpretations are amply justified.

Cardiology.

Growth of Our Knowledge of Heart Disease. By R. O. Moon, M.A., M.D., F.R.C.P., Consulting Physician to the Royal Waterloo Hospital; Physican to the National Hospital for Diseases of the Heart. London: Longmans, Green and Co., Ltd. 1927. Pp. 86. 3*s*. 6*d*.

Dr. Moon's sketch of the history of cardiology makes agreeable reading. The author tells his story in an attractive and simple fashion, tracing the progress of knowledge from the days when the arterial pulsations were attributed to "the rhythmical efforts of the vital spirits to escape from imprisonment" up to the present time. The ingenuity of some of the classical writers in explaining the functions

of the different organs of the body almost tempts one to wonder whether they were always serious. Plato, for example, enunciates the theory that the lung was placed about the heart as a soft spring, that when passion was rife the heart might be refreshed and suffer less. Harvey's discovery so eclipsed the work of his predecessors that it is easy to overlook their contributions to knowledge. These Dr. Moon has displayed in admirable perspective. He has done specially good service in recalling the observations of Servetus, who first described very clearly the pulmonary circulation and pointed out the function of the lungs in aerating the blood (and incidentally suffered martyrdom at Geneva for his heretical opinions).

When we come to more recent times it is more difficult to assess the work of different physiologists and clinicians at their true value. On the whole, Dr. Moon's attempt to do so is admirable. The name of Marey, whose researches in the physics of the circulation were of outstanding merit, is not mentioned, but he will doubtless find a place in a future edition. Cardiology is such a fundamental part of medicine that a survey of the gradual building up of the modern conception of heart disease will interest all doctors.

PULMONARY TUBERCULOSIS.

Its Etiology and Treatment. Second edition. By DAVID C. MUTHU, M.D. Brux., M.R.C.S., L.R.C.P. London: Baillière, Tindall and Cox. 1927. Pp. 381. 12*s*. 6*d*.

THE worthy Duke of Queensberry, when asked to give his opinion of the "Beggar's Opera," observed: "This is a very odd thing, Gay; I am satisfied that it is either a very good thing or a very bad thing." A similar judgment might be pronounced on Dr. Muthu's book, a second edition of which has been published, for if this is not a good book it is a very bad book. A great part of it is devoted to maintaining the thesis that the tubercle bacillus is the effect and not the cause of tuberculosis. Dr. Muthu almost denies the bacillus the right to a name in suggesting that it may be the offspring of the pneumococcus (p. 51) and the brother of the gonococcus (p. 52). He holds that abnormal metabolism, the result of faulty hygiene, gives rise to changes in tissue cells which are thereby converted into morbid bacteria, and that these are thus the product of the body in which they are found. He states that the attempt "to connect epidemics with specific micro-organisms has not been successful." He insists that we can have plague without rats, malaria without mosquitoes, and tuberculosis without tubercle bacilli. He has seen cases of cholera and bubonic plague occurring "through sheer fright or nervous fear," and claims that others have noted outbreaks of small-pox, erysipelas, and even hydrophobia "propagated by grave nervous apprehension."

Dr. Muthu blames the materialist blindness that prevents us from recognising that tuberculosis can be caused by fear "without the intervention of micro-organisms." Tuberculosis is the result of malnutrition and this is caused by faulty social conditions. "We must decide," he writes, "whether tuberculosis is an infectious or social disease. We cannot have it both ways . . . while believing in contagion we cannot consistently swing round and attack poverty, alcohol, bad housing, low wages, and other social evils." Would he also maintain that those who believe alcohol to be the cause of drunkenness cannot consistently object to slums? Is he not himself having it both ways when he states that a parental history of tuberculosis is as common among persons who show no evidence of tuberculosis as it is among those who have definite clinical disease (p. 38), and that the children of tuberculous parents are more often tuberculous than those of normal persons (p. 80)? No one familiar with the problem of tuberculosis will deny the importance of poverty, bad housing, bad feeding, and intemperance as factors that may determine its spread. Much that the author has to say on these subjects is true, but when he assumes the rôle of prophet his ready utterance betrays him. A tendency to exaggeration is evident in such a statement as that "the Empire has grown at the expense of the health of the people." Where was the Empire in the days of the Black Death, a pestilence due, if we are to believe Dr. Muthu, not to the plague bacillus but to faulty hygiene? What growth had it attained in the year of the Great Plague?

A distinguished surgeon has stated that this is a book "to make one think." Dr. Muthu is right in his contention that the study of disease should not begin and end in the laboratory. He is right in his insistence that the study of tuberculosis should involve that of heredity, sociology, biochemistry, psychology, and even ethics. But study that is not based on research is profitless, nor are "the intuitions of the mind and visions of the spirit" of any avail if we fail to appreciate the meaning and value of evidence.

THE FITZPATRICK LECTURES.

The History of British Midwifery from 1650 to 1800. By HERBERT SPENCER, M.D., F.R.C.P., Emeritus Professor of Obstetric Medicine in University College, London. London: John Bale, Sons and Danielsson. 1927. Pp. xxiv.+185. 15*s*.

A FULL abstract of the FitzPatrick Lectures, delivered last year before the Royal College of Physicians by Dr. Herbert Spencer, appeared in THE LANCET of Nov. 12th. These lectures have now been published in extended form. Too often the more specialised parts forming the "corpus" of the history of medicine have failed to give satisfaction because the writers have lacked either experience in the examination of records or any real practical knowledge of their subject. It is, therefore, fortunate that the work of writing the history of British midwifery has fallen to the lot of Dr. Herbert Spencer, for while his obstetric experience is vast he has devoted much of his spare time to the study of the history of medicine. He is, therefore, doubly equipped for the task, and the book he has produced is an excellent piece of historical writing.

Dr. Spencer adopts the biographical method, and while explaining the advances made in the seventeenth and eighteenth centuries, he tells us much that makes delightful reading concerning the lives of those who were pioneers in obstetrics. The book is written in a vigorous style. We congratulate the author upon the production of a volume which will take its place in the ever-increasing library of books dealing with the history of British medicine. The work takes us no further than the year 1800, but up to that date the task has been well performed. We look forward to a sequel bringing the story up to date.

MUSCULAR MOVEMENT IN MAN.

The Factors Governing Speed and Recovery from Fatigue. By A. V. HILL, Foulerton Research Professor of the Royal Society. New York: McGraw-Hill Book Company, Inc. 1927. Pp. 104. 12*s*. 6*d*.

THIS book contains the George Fisher Baker lectures delivered by Prof. A. V. Hill at Cornell University in the spring of 1927. It deals with the physiology of muscular exercise from the point of view of athletes, and is based largely on observations made in England and America (some being on the athletes of Cornell) by Prof. Hill and his colleagues. In the first five chapters the author describes the method of calculating the amount of energy produced during exercise from measurements of oxygen consumption, and discusses oxygen requirements, oxygen debt, buffering in the muscles, and the respiratory quotient. In considering the factors which determine the oxygen intake reference is made to the extraordinary amount of work which the heart may be called upon to perform. The next five chapters contain various mathematical calculations bearing on the maximal speeds attainable over different distances and the mechanical efficiency of the muscles. An

ingenious device is employed for accurate timing over short sections of the course, the runner carrying a magnet which induces currents in coils placed by the side of the track, the currents being recorded in a galvanometer. The last five chapters deal with heat production and other phenomena observed in isolated frog's muscle; and a viscous-elastic model is described, the properties of which closely simulate those of skeletal muscle. The study of muscular movement does not arouse widespread enthusiasm among students when it is demonstrated by a frog's sartorius lying on a thermophile; but the application of physiology to athletics awakes a new interest, and even those who are incapable of following all Prof. Hill's mathematics can hardly fail to be fascinated by his story of muscular movement in man.

NASAL NEUROLOGY, HEADACHES, AND EYE DISORDERS. By GREENFIELD SLUDER, M.D., F.A.C.S., Director of the Department of Oto-Laryngology, Washington University, St. Louis. London: Henry Kimpton. 1927. Pp. 428. 50*s*.

DURING the last 10 or 15 years Prof. Sluder has devoted much attention to certain nervous disorders, especially some forms of headache, arising from intranasal disease, or at any rate influenced by intranasal treatment. He has written numerous monographs on various aspects of the subject, and has now brought this material together in one volume. Dr. Jonathan Wright contributes a short preface on chronic hyperplastic inflammation within the nose, a condition which Prof. Sluder believes to be at the bottom of many of the disorders discussed in the body of the work.

The book is a large one, and not only exacts, but repays, close and careful study. The first condition described is "vacuum frontal headache with eye-symptoms only," which the author defines as a low grade, unending headache established by closure of the frontal sinus, without nasal symptoms or signs—i.e., obstruction or secretion. It is made worse by use of the eyes, and these patients have ocular symptoms only; the air is partly absorbed in the sinus and the negative pressure causes the walls to be sensitive. The thinnest part of the wall is at the pulley of the superior oblique muscle, and the nasal origin of the trouble is revealed by tenderness at this point and internal and posterior to it (Ewing's sign). The author believes that the mechanism of the closure is a combination of unfavourable anatomical settings with hyperplastic changes in the soft parts and bone, and he provides a very thorough description of the anatomy of the infundibular region of the nose. The treatment he recommends first is to apply astringents to this region, and he relates a case in which this kind of headache of five years' duration was permanently cured by application of 2 per cent. silver nitrate about 12 times over a period of three weeks. If this fails, he frees the inlet to the anterior ethmoidal labyrinth, at the same time removing the anterior two-thirds or three-fourths of the middle turbinal, by a somewhat difficult operation involving a very high incision, 2 mm. from the cribiform plate. The results of this operation are reported in six cases, but it would have been very helpful to other rhinologists had Prof. Sluder indicated how frequently a cure may be expected from simple and how frequently from operative treatment. The relative frequency of this kind of headache is difficult to estimate, and all experienced rhinologists will have met cases of headache of all kinds temporarily "cured" by all kinds of operation. It will be a step in advance if Prof. Sluder's description enables the rhinologist to identify one type curable by comparatively simple methods.

Anterior ethmoidal, that is to say naso-ciliary, neuralgia is a rarer condition identified by the author's clinical description; it is due to the anterior ethmoidal nerve, and the pain ceases at once on application of cocaine to the point of entrance of the nerve into the nose; the condition may be treated by injecting the nerve in this situation. A long chapter is devoted to nasal (spheno-palatine or Meckel's) ganglion and the neuroses traceable to it. The most direct of these is the "lower half headache," with pain in the roof of the nose, upper or lower jaw and teeth, the eye, and the ear, especially at a point 2 inches behind the mastoid; the "sympathetic syndrome" is much more complex and includes, besides rhinorrhœa and photophobia, an astonishing variety of symptoms, whose connexion with the spheno-palatine ganglion it is impossible to trace. Prof. Sluder gives full details of the method of injection of the ganglion. The final chapters relate to his technique for opening the maxillary antrum, and to the subject of orbital abscess, neither of which have any bearing on the contents of the rest of the book, and might have been omitted with advantage. A notable feature of the work is the detailed anatomical study of the regions concerned, and it is profusely illustrated.

The book contains much to interest, not only the rhinologist, but the ophthalmologist, neurologist, and general physician.

DIPHTHEROIDS AND STREPTOCOCCI.

Annals of the Pickett-Thomson Research Laboratory. Vol. II., No. 2, pp. 175; Vol. III., pp. 301. Edited by D. THOMSON, O.B.E., M.B., D.P.H., and R. THOMSON, M.B. London: Baillière, Tindall and Cox. 1927. Price per vol., 42*s*.

THESE two volumes comprise studies of the diphtheroid group of bacteria and of the streptococci, made upon rather unconventional lines. The authors have been at immense pains to abstract the literature of the subject, and the results of this occupy the major portion of both volumes, which are thereafter supplemented by some account of their own views and personal investigations. As regards the latter, their method in the case of the diphtheroid bacilli is to catalogue each species which they have met with, recording the ordinary morphological and biological features, and then to photograph the organisms and to reproduce the photographs of colony form and microscopical appearances, which they believe to be of great importance. Over two hundred photographs of diphtheroids are reproduced. The criticism which most bacteriologists will make against this procedure is that too great confidence is placed on the permanence and fixity of morphological characters which, it is generally held (though perhaps with over-emphasis), are of little or no reliability in comparison with biological tests.

The volume which deals with the streptococci is also essentially a literary review of the subject rather than a serious contribution of original work. Out of a total of 300 pages of letterpress, 250 are of this nature. There follows a short article by Dr. Warren Crowe, upon his scheme of streptococcal differentiation, and the book is completed by a bibliography and 57 full-page half-tone and colour plates. The bibliography includes references to more than a thousand original papers, a fact which bears witness to the wide reading and inexhaustible energy of the editors. Many of the papers are abstracted copiously, and long quotations, sometimes occupying several pages, of the more important ones occur. In fact, as a résumé of what has been written and said about the vexed question of streptococcal activities and classification, no single review has ever been published which approaches this, and the volume, therefore, has considerable value as a work of ready reference.

With regard to the original matter in the book, the authors have collaborated with Dr. Warren Crowe in propounding a scheme of classification based primarily upon colour changes in "chocolate" media containing heated blood. They describe five main groups upon these grounds with a total of 20 sub-groups which emerge when hæmolytic ability, colony form, and morphology are considered. Within these sub-groups they differentiate types upon the basis of sugar tests. This classification is supplemented by the reproduction of the photographic characters of colony form and microscopic appearance of over a hundred strains, each of which is considered a distinct

species. That these differences exist under the conditions of observation is beyond doubt, but the larger question of whether their significance is that which the authors attribute to them remains open. It would be possible for any sufficiently ingenious and patient person to classify the pebbles on the seashore into innumerable species if their individual characters were observed with sufficient detail.

PRACTICAL BACTERIOLOGY, BLOOD WORK, AND ANIMAL PARASITOLOGY.

Eighth edition. By E. R. STITT, A.B., Ph.D., M.D., Rear-Admiral, Medical Corps, and Surgeon-General, U.S. Navy. London: H. K. Lewis and Co., Ltd. 1927. Pp. 837. 24*s*.

THIS is essentially the practical pathologist's handbook. There is hardly a laboratory of any size in the English-speaking world in which it does not hold an honoured place—a place, moreover, from which it is frequently removed for reference. The eighth edition is of the same format as its immediate predecessors and is only slightly larger. The author manages in succeeding editions to pack increasing amounts of information into the book, with only a very slight increase in bulk; this can only be achieved by a masterly utilisation of every square millimetre of available space, even to the insides of the cover and the fly-sheets. The new edition has been brought thoroughly up to date. In the chemical section the tests for liver function are competently dealt with and the technique for the van den Bergh reaction, both quantitative and qualitative, is fully set out. In the section on blood the new knowledge on the platelets and the hæmorrhagic diatheses is ably summarised. The section on grouping and matching of blood constitutes the only exception to the admirable brevity and conciseness elsewhere throughout the book. The subject is made rather more involved than necessary, and in grouping and matching the unnecessary complication of citrating and spinning out the red cells is advocated. It is interesting to note that Admiral Stitt still holds that evidence that the common cold is "catching" is "academic." This seems to indicate some individual peculiarity of experience on his part.

BIRTH INJURIES OF CENTRAL NERVOUS SYSTEM.

Part I. By FRANK R. FORD. Part II. By BRONSON CROTHERS and MARIAN C. PUTNAM. (Medicine Monographs. Vol. XI.). London: Baillière, Tindall and Cox. 1927. Pp. xiii.+164. 18*s*.

IT is surprising that so little has been written on the subject dealt with in this monograph. In this volume two papers by different writers have been brought together, the first on Cerebral Birth Injuries, by Dr. F. R. Ford, of the Johns Hopkins Hospital; and the second on Cord Birth Injuries, by Dr. Bronson Crothers and Dr. Marian Putnam, of Harvard. Dr. Ford's paper does little more than define the subject, and it is to be hoped that he will continue his work, for an adequate presentation from the clinical standpoint is badly needed. He describes the needful spadework and how the cases of birth injury are being separated off from those of congenital and developmental defect. For instance, he says: "Convincing evidence has been gathered that the congenital diplegias which constitute by far the largest group of infantile spastic palsies, as seen in the pediatrics department, are not to be attributed to meningeal hæmorrhage at birth, but are the result of various pathological processes of intra-uterine origin." With this view neurologists in this country were already familiar from the work of Dr. James Collier, to which there is made abundant reference. Hydrocephalus also, according to Dr. Ford, is in most cases not the result of injury of the brain at birth. When he has disposed of two great groups of cases the author has found few left to describe, but in our opinion he has devoted insufficient space in his paper to the important remainder which really form his subject. He discusses approximately 50 cases in which the diagnosis of intracranial birth hæmorrhage was made or suspected. Out of the whole group only seven survived, and of those seven, only one developed any permanent symptoms. Dr. Ford says: "The common diffuse meningeal hæmorrhage, which is not large enough to cause death, apparently leaves no residuum in the overwhelming majority of cases. The real birth injuries to the brain are caused by the rarer intracerebral hæmorrhages and necroses, by depressed fractures with laceration of the brain, and, undoubtedly, by some more or less encapsuled meningeal hæmatomas which compress and soften the cortex." We cannot agree that such cases are rare, and it is precisely their clinical pictures which require to be defined and correlated with the pathological conditions.

The more limited subject of cord birth injuries has been excellently handled by Drs. Crothers and Putnam; their paper is most instructive. It is surprising that they should have been able to collect 28 cases of this kind within a few years, for these cases seem to be rare in this country; presumably their relative rarity must depend on some difference in obstetric technique. Dr. Crothers and Dr. Putnam show that they are due to severe traction on the legs and trunk in cases of breech presentation; as a result of such "unphysiological" force the spinal cord is torn, and the resulting syndrome depends on the extent and level of the injury; doubtless the patient's general condition also has some influence on the vitality of the distal portion of the cord. The authors are careful not to throw blame on obstetricians, but they say: "The striking contrast between the apparent incidence of injury and the almost total ignoring of the subject by writers of obstetrical text-books justifies us in suggesting that a definite shift of emphasis is desirable." These papers together form an important contribution to the subject of birth injuries of the central nervous system. The book is beautifully got up.

AIDS TO BIOCHEMISTRY.

By E. ASHLEY COOPER, D.Sc.Lond., F.I.C., A.R.C.S.Lond., and S. D. NICHOLAS, B.A.Oxf., A.I.C., Lecturers in Chemistry, University of Birmingham. London: Baillière, Tindall and Cox. 1927. Pp. vii.+188. 4*s*. 6*d*.

ONE who attempts to write on "Aids to Biochemistry" in a small volume of some 180 odd pages must be an optimist. In the first place, biochemistry is composed of so many different branches extending from chemical physiology and pathology on the one hand, down to leather-tanning industries on the other, that it can only be possible to supply aids to one branch of the subject at a time. In their preface the authors state that the book is intended to present the general principles of biochemistry to medical and science students, so that they have more or less committed themselves to the physiological side of biochemistry; but they do not show themselves to have a broad conception of the subject as a whole. For instance, although the sections dealing with the pure chemistry of the fats, carbohydrates, and proteins are fairly clear and form an adequate summary, the physiological aspects of these bodies are not considered at all. The authors may have felt that lack of space prevented the consideration of that side of the question, in which case it was surely a mistake to include a summary of the chemical aspects of some of the alkaloids with which the medical or physiological student is but little concerned. The space would have been much better employed in the consideration of metabolism. Again, the chapter on colloids is so condensed as to be practically useless, since the more important classification is, according to most people, the separation of the colloidal solutions into lyophilic and lyophobic. This important point is not mentioned.

The authors have undertaken a difficult task. They have written far too much from the purely

chemical standpoint for the book to be of practical service to medical and science students. Their book would have been of greater value if the chemical had been better balanced by the physiological aspects of biochemistry.

ANTE- AND POST-NATAL WELFARE.

The Principles of Antenatal and Postnatal Child Hygiene. By W. M. FELDMAN, M.D., M.R.C.P. Lond., F.R.S. Edin. London: John Bale, Sons and Danielsson. 1927. Pp. 743. 25*s*.

AN adequate summary of the contents of this remarkable compilation can hardly be given in a small space, owing to the diversity of the material which has been assembled. It is intended both for the lay and the medical public, and especially for those who are concerned with some branch of ante- or postnatal welfare. Information is given on every aspect of child study—historical, literary, biological, and practical. For example, an historical survey of child welfare ranges from Babylonian times to the present day, and is illustrated by photographs of classic tablets bearing on the subject, and of a large number of pediatrists of past and present years. A chapter on heredity contains a concise summary of the principal theories, and a discussion of the application of Mendelian laws to disease in general and to mental defect in particular. Another chapter on biometrics presents the essentials of the statistical method to such readers as possess some knowledge of the higher mathematics. The theory of nutrition, the practice of feeding, prevention of disease, physical and mental development, and many other branches of child study are depicted in like manner, the accounts being valuable, yet not so technical as to limit their utility to purely professional readers.

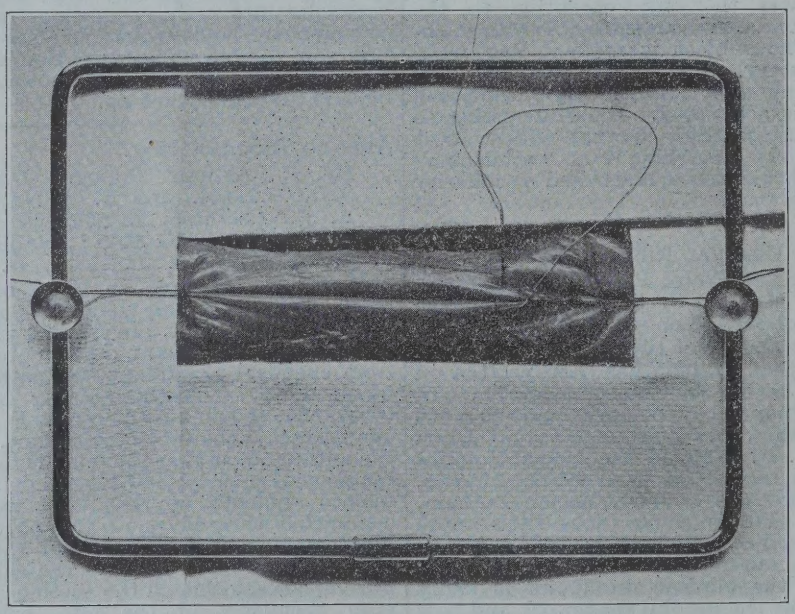
Dr. Feldman may be congratulated on having produced a volume which is original and attractive.

New Inventions.

NEW "LOOP TRACTOR" FOR USE IN GASTRO-INTESTINAL ANASTOMOSIS.

MANY surgeons to-day consider that there is a real element of danger to the patient in applying any form of clamp, even if rubber-protected, to an already partially devitalised intestine for the purpose of doing an anastomosis. The clamp is often applied for a period of from one to two hours or less, depending upon the dexterity of the surgeon. The degree of compression exerted will necessarily vary with the judgment of the operator.

Deaths from perforation or hæmorrhage due to necrosis occurring on the line of the constricting clamp have been recorded in several instances in the hands of thoroughly experienced surgeons. The cause of death was discovered at autopsy. Clamps, as usually applied, impede the operation, obscure the bleeding points, and make accurate closure at the angles of the anastomosis especially difficult. One surgeon told me he had abandoned the use of clamps entirely on account of the above-mentioned complications.



Loop tractor for gastro-intestinal anastomosis.

It has been the custom where clamps were not used in doing such operations to suspend the loops at either end by a suture grasped in forceps and held by an assistant whose hands, at best, are unsteady and in the way of the surgeon. The tension is variable and uncertain, and the suture line as a result is often imperfect. The device described overcomes all the defects above mentioned and releases the assistant for more important duties.

The instrument which I have devised will, in my opinion, perform very well the work of the clamp and is devoid of these dangers. In addition, where clamps are not used, bleeding points can be seen and ligatured before the anastomosis is completed, thus reducing the danger of post-operative hæmorrhage. Before opening the intestine it is advisable to strip its contents downwards, while the stomach, if safe to do so, should be emptied before operation.

The illustration shows the "loop tractor" in use. Its object is to suspend the intestinal loops in a taut position for suturing, and it consists of a metal frame 5 inches by 7 inches, rectangular in shape, and having a holding button situated at the middle of either end. The button is seated closely on the frame so that a suture passed around it once grips without tying. A fine linen-holding suture is the one of choice for this purpose. The frame is placed to surround the abdominal incision and rests on the sterile towels; the loops of intestine are brought up through the frame and the desired length of each loop is picked up with tissue forceps. The loops are then brought parallel to each other and a linen suspensory suture passed through a small bite, of peritoneal and muscular coats only, at either end of the anastomosis. The ends of these sutures are grasped and drawn firmly in opposite directions and wound around the button on each end of the frame, as shown in the illustration. Thus the loops are held firmly on the stretch while stitching is being done.

After thoroughly testing the forms of clamp I have come to the conclusion that this method renders these operations less difficult, secures a greater degree of safety to the patient, and that the loop tractor does the work of an assistant and does it more efficiently.

WARREN H. LANG, M.D., F.A.C.S.
Vancouver, B.C.

THE LANCET.

LONDON: SATURDAY, JANUARY 7, 1928.

PUERPERAL INFECTION.

THE report by Dame JANET CAMPBELL on the Protection of Motherhood,[1] to some of the general aspects of which we have already called attention,[2] will be read with special interest by those engaged in obstetric practice, for in spite of all the measures that have been taken since the war the maternal mortality-rate remains but little altered, and sepsis is still responsible for approximately half the deaths in childbirth. The overwhelmingly prevalent organism in puerperal infections is the streptococcus. This field of bacteriology has been widely explored in recent years, and no case has been made out for the existence of a specific puerperal streptococcus. Classification of the various strains and types of organism isolated from cases of sepsis has been impeded by a lack of a nomenclature common to the different laboratory workers. The most recent work from St. Bartholomew's indicates that a preliminary grouping into hæmolytic and non-hæmolytic varieties is unsatisfactory, since the property of hæmolysis varies within fairly wide limits, according to whether the cultures have or have not access to oxygen. If this work is confirmed, the identification of the infecting organism becomes an even more complex problem than had appeared, for classification based on morphology and specific cultural characteristics is open to many objections, and even the property of virulence varies with the laboratory animal employed. Bacteriological investigation of the vagina and cervix during pregnancy indicates the presence there of streptococci in a small proportion of cases; it is commonly stated that these are not the organisms which cause puerperal fever, and the statement is made the basis of an argument against autogenous infection. That autogenous infection cannot, however, be positively excluded is proved by the sudden and definite rise in the puerperal septic rate which occurred in 1919–20, a rise which coincided with demobilisation following the armistice. The occurrence pointed strongly to the conclusion that the infected male urethra can and does infect the female genital tract; such an obvious potential source of infection raises the question of the advisability of instructing the public on the subject of coitus during pregnancy. French observers have found streptococci on the male genital organ in the absence of any venereal infection. These are arguments more forcible than any based on the morphology or even on the cultural characteristics of isolated streptococci, and they need for their proof or disproof such extended research as might be organised from the offices of the Public Health Committee of the League of Nations. For if once it can be established that the causative organism is not generally present in the genital tract before delivery, the problem is narrowed down to that of how it gains entrance during parturition or the puerperium. Not that the mode of entry is then a simple problem. The development of septicæmia after a labour conducted without internal examination or interference of any description is familiar to every obstetrician. Small epidemics arise now and then in lying-in hospitals and homes, where the technique is apparently aseptic. In the present report to the Ministry evidence is forthcoming of another mode of infection which has long been suspected—namely, from the infected air passages of the attendant. The throat and nose are well-recognised sites of the pyogenic streptococcus; here is the record of more than one epidemic of puerperal fever attributed either to the nose (empyema of the antrum) or the throat (septic tonsillitis) of the attending midwife or pupil. We know of evidence, not mentioned in the report, incriminating bedding as a source of puerperal infection.

Enough has been said to indicate the very diverse and complex nature of the mode of infection in puerperal fever, a consideration to be borne in mind when the statement is made that this is a preventable disease. Admittedly it is preventable, but prevention entails far more than the application of antiseptics to midwifery, of paramount importance though this is, and far more than the extension of antenatal clinics or of hospital facilities for lying-in women. Until such time as we are in a position to prevent the entry of organisms into the genital tract, the first step in the prevention of the disease is to raise the resistance of the patient to the prevailing organism. It is essential for us to know what is the best specific prophylactic measure to employ for the prevention of streptococcal infection, how long it takes to acquire such immunity, and what is its degree and duration. As yet we have no exact knowledge on these points. If the prophylactic measures now available are meagre, our knowledge of the therapeutic measures which can be usefully employed, once the infection is established, is even more so. In reporting to the North of England Obstetrical and Gynæcological Society in 1926 a committee appointed to investigate puerperal blood infections stated: "The committee have been faced with the difficulty that a variety of different methods have been employed in almost every case, and they feel it is quite impossible to express a definite opinion as to the efficacy of any particular method." The same criticism might have been applied to the treatment of eclampsia before the Eclampsia Committee of the Royal Society of Medicine began to take the matter in hand in 1924, since when cases were treated on more uniform lines and results of comparative value obtained. In the London area an attempt at coördination has been made by grouping cases of puerperal fever into two main hospitals of the Asylums Board, under the care of an obstetric consultant, and the time is ripe for a more general extension of this principle. Theoretically two quite different lines of treatment are available. The one in more general use in this country is to raise the resistance of the subject by autogenous or stock vaccines, and by the use of sera and simple or immuno-blood transfusions. The other, more frequently employed in America than in this country, is to render the blood unsuitable for the growth of organisms by injecting chemical substances such as mercurochrome. We need a controlled series of investigations comparing these two lines of treatment, and the researches of L. E. COLEBROOK suggest a line along which such an investigation might be carried out. When it is demonstrated by his methods that the leucocytes have lost their power of attacking organisms, the "American method" might be employed. When it is found that this property is retained though in diminished degree, an attempt might be made both to produce an artificial leucocytosis and to increase the circulating antibodies.

[2] THE LANCET, 1927, ii., 1352.

We must admit that, while some gaps in our knowledge of puerperal fever have been filled, many still await solution; we know, indeed, little more of the pathology of the disease than did CHARLES WHITE or SEMMELWEIS.

GASTRO-DUODENAL ULCERATION.

PEPTIC ulcer is a curious affection which has baffled all attempts to elucidate its ætiology. Many surgeons following the teaching of the Mayo Foundation, based upon the experiments performed in the first instance by E. C. ROSENOW, regard the lesion as set up by streptococci which have travelled from some other focus in the body, living in which they have, by some mysterious and unexplained mechanism, acquired a special affection for the tissue of the gastric wall. L. R. BRAITHWAITE, in this country, has shown how lymph from the appendix may, in disease, travel up to the region of the greater curvature of the stomach, and other surgeons have seen in this the path by which streptococci causing appendicitis reach the stomach to cause gastric ulceration. This alluring hypothesis, however, is not satisfying to the critic who is aware that the histology of gastric ulcer is as unique as the reaction of the tissues to the tubercle bacillus, and quite unlike the picture of the defence set up to streptococci lodged elsewhere in the body. Neither are we quite sure that high acidity is a necessary condition for ulceration to occur, even if it is fairly certain that diminished secretion by the stomach is unfavourable to its onset. This honest doubt as to the causation of gastro-duodenal ulceration is reflected in the perennial argument and dispute which centres around the treatment of this condition, and is well illustrated in the proceedings of the Washington meeting of the American Medical Association which are now available.[1] As usual there were strong advocates of radical resections in all cases, and others who were only forced to adopt such measures after simple methods had failed to cure the patient. R. LEWISOHN (New York), for instance, contended strongly for routine resection in all cases, and in this he was supported by G. W. CRILE (Cleveland) so far as gastric ulcers are concerned—a position taken up by a large number of English surgeons.

The greatest difference of opinion occurred over the treatment of duodenal ulceration. C. H. MAYO and D. C. BALFOUR (Rochester, Minn.) expressed firm conviction of the inadvisability of resection of the duodenum. Their experience is so large and agrees so closely with that of Sir BERKELEY MOYNIHAN that great weight must be attached to it. Yet from time to time accounts appear of series of cases where gastro-jejunostomy has failed to bring about such good results. E. R. ARN (Dayton, Ohio), at the Washington meeting, spoke of having studied 200 cases of gastro-jejunostomy, performed for some lesion in the duodenum, which had subsequently come under his care because of persistence of their symptoms, or because of the occurrence of hæmorrhage or perforation; in all of these when the abdomen was reopened the anastomosis appeared to have been performed satisfactorily. Other observers have found that the number of poor results from gastro-jejunostomy for duodenal ulcer increases as year by year elapses from the time of the operation. Evidently further study of this question is required. If in the long run resection should prove more effective it is reasonable to suppose that technique would be evolved which would eliminate some of its present dangers. All surgeons agree that a large resection should be performed when marginal or jejunal ulceration has followed gastro-jejunostomy, and that resection should be attempted if possible whenever the original ulcer has remained unhealed, thereby tacitly admitting the greater efficacy of the more severe operation. Whether a radical policy ought to be adopted in the first instance can only be decided by more complete investigation than has yet been made. A great advantage of duodenal resection for the patient is that he need not, as after gastro-jejunostomy, take any special care about his diet.

One thing, however, is certain. The view is gaining ground that neither duodenal nor any other form of peptic ulcer should receive surgical treatment until a thorough medical cure has been tried. A good illustration of this is given in a paper which we publish in this issue by Prof. H. MACLEAN and two of his colleagues at St. Thomas's Hospital. By the intelligent use of intensive alkaline treatment, combined with a suitable measure of rest, practically all uncomplicated ulcers have in their experience been cured in a comparatively short time with little or no discomfort or inconvenience to the patient. The alkali used is the familiar mixture of three carbonates—soda, magnesia, and bismuth—a teaspoonful of the powder being given in milk, at first two-hourly by day and as often as necessary by night. This treatment, which has often shown good results after other methods have failed, has been controlled by X ray observation revealing from week to week the steady filling up of the ulcerous crater until it is completely obliterated. Some of the radiograms reproduced with Prof. MACLEAN'S paper are almost diagrammatic in their precision. While, then, it is possible that resection of the duodenum may become the correct surgical treatment for ulcer in this situation, it is more sure that when real knowledge of the disease is acquired some simple non-operative measure will be substituted for large resections of the stomach and for physiologically disturbing anastomoses between segments of the alimentary canal. Surgery, our standby in the resistant case, will then only be called upon to relieve the neglected patient.

THE REGISTRATION OF MEDICAL STUDENTS.

AT the last meeting of the General Medical Council a Report was presented by Sir HUMPHRY ROLLESTON, Chairman of the Education Committee, on the Revision of the Regulations for the Registration of Students, which dealt with a matter whose difficulties are not generally comprehended. Earlier in the year the Committee had been instructed by the Executive Committee to obtain further information in regard to examinations instituted by the various bodies, and this information was attached as an appendix. A feature of the Report was the making clear that University matriculation admitting to the faculties of arts or pure science would be ipso facto recognised, while in other faculties the certificate must bear evidences of passes of the matriculation standard in four specified subjects. The continued recognition of the examinations of the College of Preceptors was justified in the Report by the publication of a letter from the Dean of the College, expressing willingness to modify the requirements of the College in order to bring its examinations into line with those of other bodies. There is no doubt that the College of Preceptors, and equally the Scottish Educational Institute, fill gaps in the secondary education scheme of the countries, and this fact has been properly admitted.

The registration of medical students is not compulsory, and the instructions of the Council are worded as recommendations thus :—

1. Subject to such exceptions as the Council may from time to time allow, every medical student, at the commencement of his studies, should be registered in the manner and under the conditions set forth in the regulations.

2. Before registration as a medical student every applicant should produce evidence that he has attained the age of 17 years.

3. The minimum standard of general education required of applicants is that of a university matriculation or entrance examination in the faculties of arts or pure science. In other faculties the examination must be of the same standard and include the subjects prescribed in the regulations.

4. Before registration as a medical student every applicant should be required to have passed a recognised examination in general education, and, *in addition thereto*, an examination (theoretical and practical) in elementary physics and elementary chemistry conducted or recognised by one of the licensing bodies.

5. A student who has diligently attended an approved course of instruction in elementary biology at a secondary school or other teaching institution recognised by a licensing body may be admitted to the professional examination in elementary biology immediately after his registration as a medical student.

6. The commencement of the course of medical study recognised by any of the licensing bodies should not be reckoned as dating earlier than 15 days before the date of registration.

7. Every person desirous of being registered should apply to the registrar of the division of Great Britain or Ireland in which he is residing, upon a form, copies of which may be had on application to the several licensing bodies, medical schools, and hospitals, or at the offices of the Medical Council in Great Britain or Ireland; and should produce or forward to the registrar evidence that he has attained the age of 17 years, that he has passed a preliminary examination in general education recognised by the General Medical Council, and, *in addition*, an examination (theoretical and practical) in elementary physics and elementary chemistry conducted or recognised by one of the licensing bodies, and that he has commenced medical study.

The regulations set out the provisions for the maintenance of the register, giving lists of recognised examinations conducted by universities and other bodies in Great Britain and Ireland, the Dominions, and foreign countries.

The University students generally register with the Council, but such registration has not been made compulsory in spite of certain conveniences which might attach: the Examining Boards of the Royal Corporations in London apparently do not see any necessity for the proceeding, and the argument that a registration fee would be a source of revenue to the Council has lost its force in recent days, in view of the position in which the finances of the Council now stand. The student who does not register with the Council has, however, to go through exactly the same procedure elsewhere, for no Corporation will admit a candidate to its examinations without similar information to that required by the Council; in Scotland no licensing body will accept a student unless he is registered, and all registered students are accepted by the licensing bodies of the kingdom without question, while the proceeding demands no fee. The candidate has to produce evidence of having passed the necessary preliminary tests before a certain date at the time when he presents himself for his first professional examination with his papers duly signed up for admission, so that the various medical schools see that the names are duly registered with the Corporations. The pattern of the preliminary examinations admitting to the status of medical student is thus not fixed by the Council for every student in the kingdom. We do not suggest that this implies any derogation on the part of any Corporation from the standard set up by the Council; though as long as registration with the Council is not compulsory it is possible for this change to occur. Yet it is intelligible that the Corporations which provide the professional tests and grant the resulting diplomas should desire to control the conditions under which the students, whom they are later to examine for medical qualification, obtain their preliminary training. But it should be remembered that the General Medical Council is in charge, under its constitution and terms of reference, of "the courses of study and examination to be gone through . . . and the ages" of the students, "and generally as to the requisites for obtaining such qualifications," and may request the qualifying bodies for all necessary information thereon. The Students' Register is a convenient record, for the use of the medical schools, of authentic information on the preliminary training of students in the subjects of general education, and for this purpose the coöperation of the licensing bodies is needed.

Annotations.

"Ne quid nimis."

THE NEW YEAR HONOURS.

THE list of New Year Honours includes few medical names, but a good many of those who have been associated with medicine in their public work. Sir Kingsley Wood, the Parliamentary Secretary to the Ministry of Health for the past three years, becomes a Privy Councillor, and Major-General Sir Richard Havelock Charles, late President of the Medical Board of the India Office, receives a baronetcy. Knighthoods are conferred upon Mr. Frederic Hallett, formerly the secretary of the Joint Examining Board of the English Royal Colleges, whose strenuous labours in the systematisation of medical education are thus recognised; upon Mr. Percy Sargent, honorary consulting surgeon to the Ministry of Pensions, whose valuable work on brain and spinal cord injuries is well known; upon Dr. G. W. Badgerow, surgeon to the Hospital for Throat, Nose and Ear, Golden-square, and a recognised authority on his subject; upon Dr. W. J. Wanless, of the American Presbyterian Hospital, Miraj; and upon Mr. A. B. Lowry, the Chief General Inspector of the Ministry of Health. Other names in the list are those of Major-General J. S. Gallie, Deputy Director of Medical Services in the Aldershot Command, who receives the C.B.; Major R. G. Archibald, director of the Wellcome Tropical Research Laboratories at Khartum, who receives the C.M.G.; and Lieut.-Colonel C. L. Dunn, I.M.S., the Director of Public Health, United Provinces, who receives the C.I.E. Honours in the Order of the British Empire are almost confined to women. The C.B.E. has been conferred upon Miss Ellen M. Musson, R.R.C., chairman of the General Nursing Council; the O.B.E. upon Miss Jeannette Halford, founder and hon. secretary of the National League for Health, Maternity and Child Welfare, and Miss Mary Thorburn, R.R.C., matron of the Mental Hospital at Horton, Epsom. The M.B.E. has been conferred upon Miss Margaret Sloan, lately principal matron, Government Medical Department, Hong-Kong; Miss Ada Davies, lady superintendent of the Plaistow Maternity Hospital; and Mrs. F. E. Pearse, inspector of midwives and superintendent of health visitors at Oxford. The Kaisar-i-Hind medal of the first class has been bestowed upon Miss Annie S. Graham, superintendent of the Lady Reading Health School, Delhi, and upon Miss Ellen M. Farrer, medical missionary, the Zenana Baptist Mission, Punjab. The list forms no profuse recognition of medical services rendered to the country, but all will regard the names selected for honour as worthy of public acknowledgment, and we congratulate the recipients thereupon.

DEFAULTING VENEREAL DISEASE PATIENTS.

AMID the other activities, experiences, and opinions recorded in the recent report of the British Social Hygiene Council there is some useful information on the working of legislation designed to prevent the discontinuance of treatment at venereal disease centres. In Great Britain public opinion still seems unprepared for a system of compulsory notification. Locally a step in this direction was taken a year ago in the Bradford Corporation Act. When, however, the Liverpool Corporation Bill this year proposed to make notification compulsory so much opposition was developed that the proposers were obliged to withdraw the clause. Evidently many think that compulsion will merely increase the patient's bias towards secrecy and his reluctance to consult a medical practitioner. Other countries—Scandinavia and Australia, for example—have made trial of legislative compulsion and the working results have been variously estimated. In the British Social Hygiene Council's report, for instance, Dr. Everitt Atkinson describes the experience of West Australia as favourable. He states his belief that there was not a single medical practitioner in the State who failed to notify cases of discontinuance. Defaulting patients, he explains, are not prosecuted immediately. The first step is the sending of a letter personally signed by the Commissioner (the State health officer for the purpose). If this fails the patient is visited—male patients by a health inspector, female patients by a nurse. The majority of defaulters apparently resume treatment when this second step is taken. If prosecution is found essential, it is conducted in the magistrate's room in camera; if the patient thereupon is prepared to go to hospital for the necessary period, the magistrate does not impose a fine; but if the patient leaves hospital without the Commissioner's consent, the prosecution can be reopened and the full legal penalty can be inflicted. The fine, it may be mentioned, is £5 for the first offence, £10 for the second, and £15 for the third. Women, says Dr. Atkinson, take the warnings more seriously than do men; it is therefore found that fewer women are prosecuted than men. Speaking generally, he observes that the legislation has been a success in West Australia and that the syphilis-rate is going down to vanishing-point. On the other hand, as regards the State of Victoria, Dr. E. Robertson is quoted as saying that in 50 per cent. of the cases where discontinuance has been notified, the patient cannot be found, though he points out that this need not mean that none of the defaulters is under treatment. He remarks on the inadequate accommodation for treatment. The only place, it seems, where male in-patients can be detained in Victoria is the prison. As to New South Wales, Dr. R. Dick states that venereal disease is still very prevalent in spite of legislation. He speaks of 6000 or 7000 notifications in the year for a population of 2¼ millions, and he reports the usual difficulty in tracing defaulters. He significantly cites one leading Sydney doctor as having told a recent Royal Commission on Public Health that he had never notified a case. Dr. Dick gives his opinion that the powers given under the Act are valuable in spite of the many difficulties. Their effect in Queensland, where according to the 1927 report which has just come to hand, there were 309 defaulters out of 602 male patients attending the Brisbane clinic, has been that 89 returned after a written request to complete treatment while the police were able to warn 119 although no trace could be found of 74 others, while 22 had left the State. In Great Britain the same difficulties are only too well known and their solution depends upon voluntary efforts. The last annual report of the Scottish Board of Health mentioned the steps taken in Glasgow to follow up defaulters and described the value of visits by nurses. It will be interesting to watch the working of the new German law [1] which has lately come into operation. Like the English statute it enacts that treatment for venereal disease can be given only by doctors. But it goes far beyond the English Act in providing for compulsory notification and treatment and imposing penalties for wilful exposure to infection. It also legalises the sale of prophylactics and it directs the doctor to explain to the patient the nature of his illness.

RADIUM AND BREAST CARCINOMA.

AN interesting contribution to the study of the treatment of carcinoma of the breast with radium has recently been published by Mr. Sampson Handley in America.[1] Mr. Handley's theory of "centrifugal permeation" by carcinoma cells is well known, and this theory involves the belief that infection of the parasternal lymph glands proceeds coincidently with infection of the axillary lymph glands. It is possible to excise the latter, but the former are not accessible. Mr. Handley has therefore made it his practice during the last six years to insert radium tubes above the first rib and into the upper three intercostal spaces as a prophylactic measure in every primary operation for carcinoma of the breast. If the parasternal glands are not infected at the time of operation the radium treatment is superfluous; if the carcinoma has already reached the mediastinal glands, it is inadequate. If, however, the infection has reached these glands and not yet gone further, Mr. Handley believes that the use of radium will materially improve the patient's prospects, and claims that he has himself had better results since he adopted this procedure. He has also proved microscopically that destruction of carcinoma in a parasternal gland can be produced by radium. In only a single instance in the series did recurrence of carcinoma take place in an intercostal space which had been thus "protected" by radium. It is urged that this prophylactic treatment ought to be used as a routine with operations for carcinoma of the breast.

PENETRATION OF DAYLIGHT INTO BUILDINGS.

FROM the point of view of school-children and from that of clerical workers this is a matter of primary importance in relation to eyesight. A brochure issued by the Department of Scientific and Industrial Research [2] is an attempt to put the subject on a scientific footing. Weather conditions in this country are so variable that it is of little use to attempt to estimate the amount of daylight which is likely to enter a room through the window. What can be done is to define for any given spot in a given room approximately what proportion of the light that enters the room through the window is available at that particular spot. For this purpose certain technical terms are used. The "sill ratio" is the percentage of the illumination of a horizontal surface placed on the window-sill of the room, all external buildings or other obstruction being supposed removed that falls on any particular surface. The "grumble point" is what is found by experience to be the minimum tolerable value of sill ratio. The "no sky contour" marks off that portion of a room from which the direct view of the sky is visible from that from which it is not. For estimating these matters several more or less arbitrary assumptions have to be made. The amount of light reflected from the sky is an "average" amount. Average weather is taken to be weather in which the illumination of a horizontal card on an unobstructed window-sill is 250 foot candles. Since in towns there is always some obstruction the value of the light reflected from dull surfaces and whitewashed surfaces respectively has to be estimated. It is said that a sill ratio of 0·4 per cent., equivalent to 1 foot candle, is just tolerable. In the elementary schools that have been approved no desk is placed

[2] Penetration of Daylight and Sunlight into Buildings, Department of Scientific and Industrial Research, Illumination Research Technical Paper No. 7. H.M. Stationery Office. 1s.

in a less favourable position than one having a sill ratio of 1 per cent., or 2½ foot candles. Whether or not from a position in the room there is any direct view of the sky is a specially important point. Otherwise the other conditions have to be specially favourable for the lighting to be considered adequate. Architects and others will do well to study this subject, and it is well that some sort of quantitative estimation of lighting should be undertaken for their benefit, but they must bear in mind that a standard which for the normal-sighted is just tolerable, for the weak-sighted would be intolerable. A point well brought out in the brochure is the comparatively low value of the light reflected from the walls, roofs, &c., that obstruct a direct view of the sky. We have here, in fact, something like a scientific justification of the legal doctrine of "ancient lights."

REFECTION.

A REMARKABLE phenomenon has been observed independently by L. S. Fridericia[1] and his coworkers at the University Institute of Hygiene, Copenhagen, and by H. Chick and M. H. Roscoe[2] at the Lister Institute. Both these sets of workers, when experimenting with rats on diets deficient in vitamin B, found that in certain circumstances the animals began to pass large white fæces, and that when this occurred all symptoms of vitamin B deficiency were suppressed, and the rats throve and grew indefinitely; whilst animals which did not form the white fæces declined and succumbed to the deficiency in the ordinary way. Fridericia has given to this phenomenon the convenient name of "refection," and has made a very considerable study of it; the investigations of Roscoe are not so extensive, but she confirms Fridericia in a great many points and extends his observations in a few important ones. Fridericia found that the phenomenon of refection only made its appearance in a few of the rats when a number were placed on the deficient diet, but that if the white fæces from the spontaneously refected rats were fed for a few days to others on the deficient diet these latter also became refected and might remain so indefinitely; any refected rats might, on the other hand, temporarily or permanently relapse. The fæces retained the power of inducing refection when kept in the dry state for at least 5½ months. The agent, or, as Fridericia calls it, the virus of refection, would not pass the pores of a Berkefeld or of a Chamberland filter; it was destroyed when heated to 100° C. for 10 minutes, but not when heated to 80° C. for 10 minutes. The white colour of the fæces was found to be due to undigested starch, but they did not include the whole of the ingested starch, some of which was digested. The starch grains were found to be resistant to the amylase which is present in the fæces, but this amylase was able to digest ordinary starch grains; and it seems that something was adsorbed upon the starch grains which protected them from the action of the amylase; the protective agent was soluble in acid alcohol. The white fæces contained considerable amounts of vitamin B, in contrast with brown fæces which contained little or none. When rats showing refection were fed on a diet containing vitamin B, the failure to digest the starch disappeared, and it was impossible to induce refection in rats on a complete diet by adding white fæces from refected rats to their food. When carbohydrate other than starch was given to rats already refected, a decline in weight began at once, but seemed to go on more slowly than if the rat had never been refected. Fridericia advances no definite theory, but he evidently believes that vitamin B is produced in the intestinal tract of rats by the growth of a virus other than an ordinary intestinal denizen, and that the presence of undigested starch grains in the fæces is a necessary concomitant. As to the function of the starch, he hazards no conjecture.

Roscoe confirms Fridericia in his main argument, agreeing that the condition occurs spontaneously in a few only of the rats on the deficient diet, that it can be transferred to other rats by feeding them on the white fæces, and that undigested starch is present in the fæces, causing the white colour. But she clearly shows what is only inherent in Fridericia's work—that refection replaces either or both parts of the vitamin B complex in the deficient diet. This is important, as it is hardly possible to imagine that both parts of vitamin B, in the absence of which neuritic and pellagra-like symptoms develop, can be dispensed with from the diet in any other way than by the formation of these two parts by some organism in the intestine, a view which is particularly supported by Fridericia's observation that there is more vitamin B in the white fæces than in the dark ones. Unlike Fridericia, Roscoe was able to observe refection in rats which were receiving both fractions of vitamin B, and when the fractions were withdrawn the rats, being refected, remained in health. She also noticed that refected rats, when caged upon wire grids of very wide mesh, so that the fæces fell through the moment that they were passed, ceased to be refected and might die or might recover again. As it was seen that rats could actually learn to catch their fæces the moment they were passed and consume them, it was concluded that coprophagy was necessary to the continued maintenance of refection. She found that refection was impossible if there was no starch in the diet, and that it was absolutely prevented if the starch was first cooked, so that every starch grain was thereby burst.

The connexion of the condition with the presence of unbroken starch grains is thus confirmed by Roscoe's work, though she too offers no explanation of the connexion. Her results are not incompatible with a conjecture that the persistence of the unbroken starch grains is in some way conditioned by the growth of an organism which generates vitamin B in the intestinal tract, but if that is so it is not clear why refection does not always occur. Possibly only some kinds of starch are suitable or only some carry the "virus." Both Roscoe and Fridericia used rice starch only, but it is of interest to note that C. Eijkman[3] many years ago found that potato starch had some special action in preventing the outbreak of polyneuritis among pigeons where other kinds of starch had no such action. Also M. A. Boas[4] has found that arrowroot and potato starches, in contrast with some cereal starches tried, are peculiarly effective in preventing the condition of malnutrition which she has found to develop in rats fed on certain diets containing dried egg-white.

AN INTERNATIONAL COURSE IN PUBLIC HEALTH.

THE continuation course in public health, which came to an end just before Christmas, was an unqualified success, and the Health Section of the League of Nations may congratulate itself on having made a practical contribution to the health of nations. Delegates came to London from Brazil, the Crown Colonies, Czecho-Slovakia, France, Germany, Hungary, Iceland, Northern Ireland, the Irish Free State, the Netherlands, Norway, Scotland, Sweden, Switzerland, the United States of America, and Yugoslavia. The inclusion among the delegates of representatives from the British Empire proved of value to both home and foreign participants, permitting as it did a much more free and intimate exchange of views and experiences than would have resulted from formal lectures and discussions. Arrangements were in the hands of the Ministry of Health and of the Society of Medical Officers of Health, and procedure took the form of

[3] C. Eijkman: Virchows Archiv, 1897, cxlviii., 523.
[4] M. A. Boas: Biochem. Jour., 1927, xxi., 712.

lectures by eminent British and foreign authorities on a wide range of public health subjects, of discussions with the speakers, and of individual and collective tours of inspection to institutions or works of hygienic interest.

Sir George Newman's introductory lecture demonstrated the antiquity of British public health administration, founded upon the roads and baths of the Roman occupation, the Domesday Book and the Gilds, science and social reform combining to produce administrative action. A comprehensive review of national health insurance schemes in Europe, given by Dr. A. Foramitti (Austria), showed how efficiency in public health administration connotes efficiency in health insurance work. Dr. J. Smith Whitaker, on the other hand, attributed to the general practitioner the success of the British scheme, stimulated indirectly only by public health machinery. Industrial hygiene was dealt with by Prof. G. Y. Giglioli (Florence) and Dr. J. J. Buchan (M.O.H., Bradford), the former in a historical review pointing out that the retrograde influence of the Great War was counterbalanced by the introduction of physiological methods, the latter discussing the question of light, ventilation, and temperature in industry in relation to the employer and employee. Dr. T. H. C. Stevenson (General Register Office), in a paper on the national vital statistics of this country, described what may prove to be the first definite clue to the solution of the problem of cancer when he showed that grading in regional sites from the skin to the pylorus indicated that cancer was a social condition. That the recently instituted clean milk competitions had done more to educate the milk industry in the meaning of bacterial purity than have 50 years of inspection was a notable pronouncement of Dr. A. W. J. MacFadden (Ministry of Health) in a detailed discourse on the hygiene of milk. An instructive account of the legislation safeguarding food-supply was given by Dr. C. Porter (M.O.H., Marylebone), his remark that the good food regulations of foreign countries had resulted from British insistence meeting with no criticism from the foreign delegates. Prof. F. Neufeld (Robert Koch Institute, Berlin) described recent research work on tuberculosis and its application. He considered that dried dust was a very much more important means of spread than wet droplets; that bovine bacilli played no rôle in pulmonary tuberculosis; that large doses of bacilli are required to produce the disease, and that a filtrable form of tubercle bacillus was a very unlikely primary organism if it existed at all. Prof. C. Pirquet (Vienna) emphasised the importance of a little surplus of food—his only therapeutic measure—in the treatment of tuberculosis. Sunlight acted merely as an adjuvant in the immunising process by stimulating the appetite. The lectures on immunity and infection by Prof. Carl Browning (Glasgow), Prof. W. W. C. Topley (London School of Hygiene), and Surgeon-Commander S. F. Dudley embraced the problems of fluctuation in virulence and in susceptibility, velocity of infection, and herd immunity. The present position of chemotherapy from the clinical point of view was a subject in which Prof. B. Nocht (Hamburg) provoked deep interest, especially on the part of those interested in tropical medicine. Mr. K. Stouman's (League of Nations) paper on the geographical distribution of epidemic diseases demonstrated the great international importance of the health work of the League. His statement that the world was probably on the verge of an increase in the incidence and virulence of diphtheria received ample support in ensuing days from speakers from different parts of the globe. An honest and clear account of the present position of the problem of nutrition was given by Prof. E. P. Cathcart (Glasgow). In a series of four lectures Prof. Haven Emerson (New York) described the progress and present position of public health administration in America, perhaps one of his most outstanding remarks being that New York had now done all that could be done by isolation, quarantine, and therapeutic measures to counteract diphtheria, and that if a further fall in incidence was desired immunisation of children under one year of age must be undertaken and practised as commonly as small-pox vaccination. Lectures by Sir George Buchanan, Dr. F. G. Boudreau, and Dr. Norman White on the work of the League fittingly concluded the course. Fifty-two lectures in all were delivered, and in a brief résumé such as this it is impossible to do more than single out here and there some of the more salient items. The hope of the participants that the lectures should be reprinted in book form is one which we cordially endorse.

Visits of inspection were paid to the many institutions which make London such a desirable centre for a hygienic survey. The places visited included the Ministry of Health, metropolitan schools, the port sanitary authority, milk-supply depôts, Lord Mayor Treloar's Home for Cripples at Alton, a study of rural hygiene in Bedfordshire under the guidance of Prof. H. R. Kenwood, the Royal Sanitary Institute, the Institute of Tropical Medicine and Hygiene, and the laboratories of the Metropolitan Water Board. The physical and mental fatigue of six weeks' intensive study may have left the foreign participants in the course a little limp, but they were unanimous in recognising the value of the opportunity they had been afforded of getting to know the problems, the shortcomings, and the successes of their colleagues' countries and thus of acquiring a broader outlook on national health.

AN INDIAN REMEDY AGAINST DYSENTERY.

A STUDY of the pharmacological and therapeutic actions of *Holarrhena antidysenterica*, a small deciduous tree widely distributed throughout India and Burma, has recently been undertaken by Rev. Father J. F. Caius and Dr. K. S. Mhaskar, and the results published in an Indian Research Memoir. Since both the bark and the seeds of this plant have been, and continue to be, among the most important medicines of the Hindu materia medica, being used extensively in the treatment of all forms of indigestion, of dysentery, and of disorders of the lungs, there existed a need for an investigation of their biological properties by modern methods of research. This the authors have undertaken with the following result. A 1 : 5 decoction of the powdered seeds was found to have no antiseptic value when tested by its effect on the growth of colon and typhoid bacilli. It produced an increase in the tone of the plain muscle of the gut and uterus of the guinea-pig and rabbit, and the powdered seeds in doses of grs. 15 to 60 a day led to a definite clinical improvement in 57 per cent. of the cases of amœbic dysentery, in 22 per cent. of the cases of non-amœbic dysentery, and in 61 per cent. of the cases of non-dysenteric diarrhœa investigated. The seeds contained a relatively high percentage of oil, but the pharmacological agent responsible for the effects observed was not concentrated in this oil. The bark was next subjected to experiment with the result that decoctions of this were found to give pharmacological and therapeutic reactions essentially similar to those produced by decoctions of the seeds of the plant. The bark constitutes the principal medicine for dysentery in the Indian Pharmacopœia, and Indian writers are unanimous in recommending this drug. "Accordingly," it is stated, "the Indigenous Drugs Committee decided to determine the place of the bark of *Holarrhena antidysenterica* in the treatment of dysentery . . . 30 patients were treated, of whom 26 were either cured or improved." Results almost as satisfactory as these were obtained by the authors, in that 51 out of 67 cases of amœbic dysentery, 37 out of 55 cases of non-amœbic, and 9 out of 20 cases of non-dysenteric diarrhœa were definitely improved. It will be observed that these results are somewhat better than those obtained from the use of the powdered seeds, and in this connexion it is to be noticed that the authors found a much larger amount of the alkaloid conessine in

the bark than in the seeds of holarrhena. This alkaloid was extracted from the bark and its pharmacological action investigated. The results confirm on the whole those of previous workers, and the drug was found to be effective in some cases of dysentery. The question arose as to whether this alkaloid was the essential agent in producing the good resulting from the treatment of dysentery by the bark and seeds of the plant. It has been shown recently by R. N. Chopra, J. C. Gupta, J. C. David, and S. Ghosh that conessine has a specific action on *Entamœba histolytica* obtained from the stools of infected kittens, being even more active in killing this parasite than is emetine. Although we must assume that the alkaloid is largely responsible for the beneficial effects of the crude drug, yet the results of Caius and Mhaskar show that the effects of administration of the seeds or bark to cases of dysentery are not entirely explicable on this hypothesis, since "the smallest therapeutic dose of free alkaloid is quite out of proportion to the amount of combined alkaloid present in the optimum doses of either the seed or the bark—30 to 1 in the case of the seed and 2 to 1 in that of the bark." The conclusions arrived at by the authors as the result of their study are that the antidysenteric value of holarrhena compares favourably with that of any of the medicines now in vogue, that its antidiarrhœal properties are not dependent on one chemical constituent in particular but on the entire seed or bark, and that it affords a safe, cheap, reliable, and easily administered drug for the treatment of diarrhœal troubles. They recommend the daily administration of grs. 60–120 of the powdered bark in three to four portions. Results of real value to medicine are likely to accrue from studies of Indian medicinal plants such as those undertaken by the authors of this memoir, and the Indian Government may be congratulated on initiating such a line of research.

THE SNOW.

THE snow has come and gone, at all events in southern England, leaving a tale of hardship and adventure which will take the place for the present generation of the great snowstorm of 1881 for the past. Snow fell on Christmas evening in no very remarkable quantity, for nowhere was there an average of more than a level foot in depth—equivalent as everyone knows to an inch of rain—but the continuous gale from Nova Zembla or thereabouts gave no peace to the falling flakes which drifted before it until they could find rest in some hollow or other, whether railway-cutting, country lane, or domestic backyard. Our legal correspondent has dealt elsewhere with the mischief produced on the public highway; it is the domestic aspect with which we are here concerned. Falling snow offers a very convenient dumping-ground for things which one wants to be rid of, and it attracts tenants of the poorer types of house to throw into it rubbish which should go into the dustbins. Even on roads which are normally free from rubbish the snow soon becomes foul, while stall-holders in open markets frankly regard the snow as a pretext for being more than ordinarily careless with their trade refuse. Anyone who has seen the backyards of a snowbound village thaw out in the spring will realise that they tell a fairly accurate story of the habits of the local housewife, and, as the larder is rightly placed on the sunless aspect of the house, it is in its immediate proximity that the snow persists longest and the accumulation of dirt and unconsidered trifles is most conspicuous. Street hygiene did not suffer in London itself as much as might have been expected. Surveyors were careful, while snow was still falling, not only to clear a central passage for traffic, but also to keep the gutters clear, and the removal of house refuse was affected only to a limited extent. In many London areas motor vehicles are used for its removal and the difficulty is thereby reduced to a minimum. The effect on the general street cleansing is that the removal of snow replaces the more ordinary street sweeping, and in London the duty of clearing both carriageways and footways devolves on the local authority. When rock salt is used to facilitate the clearing as little as possible is applied, and the roads are washed by means of hose and water vans as soon as the thaw sets in. Local Government Board by-laws of 1877 provide that where salt is used for the purpose of facilitating the removal of any snow from any footway or pavement, the whole of the deposit resulting from the mixture shall forthwith be effectively removed. The effect of a temporary suspension of street cleansing would not appear to have any serious consequence, except that the presence of litter and refuse in the streets is unattractive. During the war in a central London borough with much vehicular traffic, the street-cleansing staff refused service for a period of three or four weeks during which very little cleansing of the thoroughfares could be effected. Efforts were, of course, made to secure temporary labour; volunteer women were employed and even the borough surveyor took a turn with the broom; but these efforts were comparatively small in their effect, and the refuse was left more or less undisturbed through the strike period, yet no ill-effect on health is known to have occurred.

SMOKING AND THE STOMACH.

THE latest reflections on tobacco-smoking may be found on p. 14 of our present issue, where Prof. Hugh MacLean and his colleagues suggest that "the profession as a whole hardly realises the excessively detrimental action of tobacco on the deranged stomach." Their belief in its evil effects, though presumably based on clinical observation, can find a good deal of support in the records of experiment. In a recent lecture [1] Prof. W. E. Dixon, after remarking that the commonest symptoms of smoking are loss of appetite and chronic intestinal catarrh, said that "nicotine and tobacco-smoking, by stimulating the autonomic ganglia, increase the secretion of the alimentary glands and later, after the smoking has ceased, depress them." Injections of saline through which smoke has been passed produce in dogs a decided increase in the flow of gastric juice, and "it is well recognised that in certain persons excessive smoking leads to this gastric hypersecretion." Prof. Dixon quotes F. Wagner as insisting that excessive smoking can produce all the subjective and radiographic appearances of duodenal ulcer, but Sir Humphry Rolleston [2] says that this tobacco dyspepsia is rather rare, being attributable probably to pyloric spasm. He points out, however, that with oral sepsis excessive salivation due to smoking may set up gastritis, and states that after a short period of increased contractility the stomach becomes paralysed under the influence of tobacco, the paralysis lasting perhaps an hour. Though these facts lend force to Prof. MacLean's plea that smoking should be forbidden to patients whose stomachs are struggling back to health, it remains uncertain whether tobacco plays an important part among the processes which cause gastric ulcers and neuroses. That it does so has often been asserted, and its action is invoked to explain the greater incidence of ulcer in men than women. The hypothesis is (to smokers) unattractive, and is fortunately not supported by the results of a small statistical study [3] that Dr. C. W. Barnett has been making at the Peter Brent Brigham Hospital in Boston. From their case-histories Dr. Barnett classified into smokers and non-smokers all the male patients with gastric or duodenal ulcer or gastric neuroses treated at the hospital from 1913 to 1926. In all there were 312 cases with a complete history, and for comparison 500 patients of similar age were selected from the general admissions. No difference

[1] THE LANCET, 1927, ii., 881.
[2] THE LANCET, 1926, i., 961.
[3] Boston Medical and Surgical Journal, 1927, cxcvii., 457.

of any importance was found between the proportion of smokers among the cases of peptic ulcer or gastric neurosis and among the controls, nor was the mean age of admission of the cases of gastric or duodenal ulcer different among the smokers or non-smokers. From this evidence, then, so far as it goes, no case against smoking can be made out. Clearly, however, the evidence does not go very far, and as Dr. Barnett points out, nothing was known about the *amount* of smoking, and the possibility of excessive smoking leading in some cases to peptic ulcer is not precluded, though not indicated by his investigation. Now that tobacco is taking the place of alcohol as the popular drug of addiction it has become very important to know the truth about these matters.

VLADIMIR BECHTEREV.

THE death on Christmas Day of Vladimir Mikhailovich von Bechterev in his seventy-third year should not remain unnoticed, for he occupied for many years the chair of psychiatry and nervous diseases at St. Petersburg, and his many contributions to neurology and anatomy are lasting witness to his scientific foresight and painstaking thoroughness. His name is specially associated with the pioneer experiments with cerebellar stimulations that first opened up an avenue of exploration along which modern investigators are still travelling. He was among the first to suggest an anatomical representation within the cerebellum of the body segments. His anatomical researches on the peripheral and central connexions of the acoustic nerve are equally familiar. In 1884 Bechterev, in the course of his experimental work, observed forced movements resulting from stimulation of the base of the forebrain in animals, suggesting to him the possibility of vestibular centres in this region. The following year he determined, with Flechsig, the peripheral distribution of the roots of the acoustic nerve; a year later he and Edinger, working independently along embryological lines, demonstrated the central terminations of this nerve. Bechterev contended that the anterior root of the vestibular nerve does not arise from the dorsal nucleus, but rather from cells situated in the vicinity of Deiter's nucleus—and in fact the nucleus angularis still bears his name. Other anatomical researches which are associated with him include the demonstration of the central tegmental tract, which descends in the neighbourhood of the inferior olive, and the line of Kaes and Bechterev, which forms part of the supraradiary zone of the cortex. Clinical neurology also is the richer for his work, and to-day the nasal reflex and the reflex of the dorsum of the foot are still coupled with his name. In 1893 he described, as a variety of chronic rigidity of the spine, a condition of vertebral ankylosis with root signs, of heredo-traumatic origin—a syndrome known to medical dictionaries as Bechterev's disease. Bechterev was born at Vyatka on the slope of the Ural Mountains, and although he studied for periods at Leipzig and Paris he spent the whole of his active life in Russia. To posterity his name will certainly rank with those of Ferrier and Hitzig as a pioneer of experimental neurophysiology.

INDEX TO "THE LANCET," VOL. II., 1927.

THE Index and Title-page to Vol. II., 1927, which was completed with the issue of Dec. 31st, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

HARVEIAN SOCIETY.—The annual general meeting of this society will be held on Thursday, Jan. 12th, at 8.30 P.M., at 11, Chandos-street, London, W.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. H. F. Stephen to be Surg. Comdr.

Surg. Lt.-Comdrs.: F. G. Hunt to *Tamar* for Hong-Kong Dockyard; and F. H. Vey to *Victory* for Portsmouth Dockyard.

Surg. Lts.: D. Duncan to *Vernon*; J. H. Nicolson to *Tiger*, temp., and to *Cornwall* (on commg. with full complement); and S. G. Weldon to *Alecto*, temp.

Surg. Lt. (D.): A. W. Wallace to *Victory* for R.N. Barracks, Portsmouth, temp.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Comdr. H. L. Murray to be Surg. Capt.

Surg. Sub-Lt. T. A. Brand to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. C. R. Sylvester-Bradley is placed on the half-pay list on account of ill-health.

Maj. and Bt. Lt.-Col. G. De la Cour, from a Professor, Royal Army Medical College, is granted the rank of Temp. Col. whilst empld. as Consulting Surgeon to the British Army.

Col. R. H. Lloyd, late R.A.M.C., is placed on half pay.

Lt.-Cols., from R.A.M.C., to be Cols.: E. McDonnell and Bt. Cols. A. H. Safford and J. W. West.

Cols., late R.A.M.C., retiring on retd. pay: G. M. Goldsmith and H. D. Packer.

Col. H. H. S. Morant, having attained the age for compulsory retirement, is placed on retd. pay and is granted the hon. rank of Brig.-Gen.

Lt.-Col. A. McMunn, having attained the age fixed for compulsory retirement, retires on retd. pay.

Majs. to be Lt.-Cols.: N. Low, A. N. Fraser, and R. H. L. Cordner.

Capt. G. T. Gimlette to be Maj. (Prov.).

Temp. Lt. O. A. Owen-Flood (Lt., Reg. Army Res. of Off., R. Ir. Fus.) relinquishes his temp. commn.

ARMY DENTAL CORPS.

Capt. H. H. Mallet to be Maj.

The undermentioned to be Lts. on prob.: N. I. Macmillan, W. P. Baxendine, A. K. Inglis, W. McD. Birse, and R. G. J. Tovey.

TERRITORIAL ARMY.

F. MacD. Walker to be Lt.

Hygiene Companies: Lt. C. M. Willcox, late R.F.A. (Spec. Res.), to be Lt.

ROYAL AIR FORCE.

Half-yearly Promotions: Wing Comdr. E. C. Clements to be Group Capt. Flight Lt. (Acting Squadron Leader) J. N. MacDonald to be Hon. Wing Comdr.

INDIAN MEDICAL SERVICES.

Capt. E. Kean resigns his commn.

Temp. Capt. C. L. Katial relinquishes his temp. commn.

Lt.-Col. W. H. C. Forster has been appointed Inspector-General of Civil Hospitals, Burma. Dr. E. Heath is to act as Lady Inspector of Factories. Dr. Fred Barretto has been confirmed as Officer in Charge, Public Health Laboratory, Poona. The services of Lt.-Col. G. W. Maconachie have been placed at the disposal of the Government of India for appointment as Inspector-General of Prisons, Bihar and Orissa. Lt.-Col. F. Stevenson has been posted as Residency Surgeon, Kashmir. Lt.-Col. A. Cameron, civil surg., has been posted to Agra; Lt.-Col. J. F. Boyd, civil surg., to Aligarh; Maj. G. T. Burke, civil surg., to Jhansi; Maj. E. G. A. Mathews, civil surg., from Aligarh to Hardoi; Dr. Gauri Nath, officiating civil surg., from Hardoi to Ballia; and Dr. Har Prasad Bajpai, officiating civil surg., from Jhansi to Hamirpur. Lt.-Col. W. A. Mearns is to resume the duties of Assistant Director of Public Health. Lt.-Col. J. Anderson has been posted as Civil Surg., Sibi. Dr. M. V. Webb, Principal, Women's Medical School, Agra, and Acting Senior Medical Officer, Women's Medical Service, and Secretary, Dufferin's Council, Countess of Dufferin's Fund, has made over charge of the office of the latter to Dr. A. C. Scott.

The Secretary of State for India has approved the grant of vacant Good Service Pensions to Lt.-Cols. W. Coates, I.M.S., retd., and C. J. McCartie, I.M.S., retd.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLVII.—TREATMENT OF ILEUS FOLLOWING OPERATIONS.

ILEUS or intestinal obstruction secondary to operation may be of two types—paralytic, when it results from failure of peristaltic action, and mechanical when it is due to some organic block of the bowel.

Paralytic Ileus.—In this variety there is paralysis of some portion of the intestine and the effect may be transitory. Such ileus may follow the reposition of large strangulated herniæ, but the most important cause of all is acute peritonitis either localised or diffuse. In this condition the intestine becomes inflamed and is unable to propel its contents.

In *mechanical ileus* the intestine may be strangulated or kinked by bands or cords, the result of peritoneal adhesions following operation, or a tear in the omentum or mesentery made by operative trauma may lead to intestinal obstruction. Ileus may also be produced as the result of cicatricial contracture affecting the wall of the bowel following an artificially made anastomosis.

Mortality.

The mortality from acute intestinal obstruction has fallen very little during recent years. The death-rate after operation in early cases is not less than 20 per cent., whilst in any large collection of cases it may reach 50 per cent. It seems to be generally agreed that the high and rapid mortality in obstruction of the small intestine is due to the absorption of toxic material developed within the bowel. Evacuation of the bowel contents is therefore of first importance, but restoration of peristalsis is also essential for recovery. If the bowels can be made to act the patient frequently recovers, whilst if they fail to act, he will die. In the late stages of fatal cases of acute peritonitis paralytic obstruction develops and this is largely responsible for the symptoms of toxæmia. The most common cause of peritonitis met with by the general surgeon is acute appendicitis. Of cases dying of peritonitis 5–10 days after operation for appendicitis probably 75 per cent. are due to intestinal obstruction, which is a most difficult and dangerous complication. If intestinal obstruction does not supervene peritonitis often yields to treatment.

The treatment of paralytic ileus has always been unsatisfactory. The efficacy of drugs such as castor oil, calomel, eserine, or pituitary extract depends on contraction of the bowel. If the bowel is paralysed these drugs will fail to act and will add to the strain on a heart already damaged by toxæmia. Enterostomy in the paralysed bowel in such cases only drains the affected loop, and therefore is of but limited value. It is, therefore, apparent that in cases of paralytic ileus attempts to stimulate peristalsis in the bowel should be avoided. The most effective measure is to give it complete rest, and thereby a chance to recover its power of active contraction. This treatment, combined with an enterostomy above the affected portion of the bowel, does undoubtedly prove successful in many cases. Enterostomy is an easy and quick operation and makes little demands on the patient's vitality. In addition, glucose and sodium bicarbonate can be run into the bowel and is absorbed better than from the rectum or elsewhere. The toxins are thus diluted, and this process is of distinct advantage to the patient.

Clinical Features.

Post-operative ileus is usually seen at two periods after operation—early, within the first two or three days, or later during the convalescent period. The treatment to be adopted will depend on the stage at which the condition arises. The management of early cases arising after operations for peritonitis due to acute appendicitis presents a most anxious and difficult problem. These cases are usually due to multiple kinking of inflamed bowel by plastic lymph. This condition chiefly affects the lower ileum, having been set up by perforation of a gangrenous appendix. The bowel becomes acutely inflamed and then paralysed by extension of the inflammation to the muscular wall. Death in these cases is due to intestinal obstruction and not to peritonitis. The clinical picture is fairly typical. The patient shows little or no improvement after operation, and the abdominal distension becomes more marked; vomiting is progressive and enemas produce no satisfactory result. About the fourth or fifth day after the operation the signs of intestinal obstruction become well marked and further operation is then essential.

Enterostomy.

When obstruction develops shortly after operation it is rarely complete and the intestine will not infrequently recover its function if given a reasonable chance. In these cases all nourishment by mouth must be entirely stopped so as to avoid further overloading of a distended bowel. Fluids should be given freely by the rectal and subcutaneous routes. Where vomiting is troublesome gastric lavage is valuable, and can be repeated as often as necessary. Morphine in doses of gr. 1/6 gives relief from pain, and in spite of apparent contra-indications will be found useful.

If improvement does not follow this treatment in about 48 hours operation will be necessary. This involves drainage of the small intestine by an enterostomy above the site of obstruction and above the level at which the bowel is paralysed. It is an extremely easy procedure and should be carried out by the following method.

Technique.—A local anæsthetic (2 per cent. of novocaine) is used. A left paramedian or rectus splitting incision just above the umbilicus is made, and the first distended loop of intestine that presents is withdrawn into the wound. This is clamped after it has been emptied, and a tube or large catheter with a terminal opening is sutured into the bowel by Witzel's method. According to this method the tube is laid for 3 or 4 inches along the bowel, and the serous and muscular coats sutured over it. The tube is then brought out through a gap in the omentum and the wound closed round it. This enterostomy of the valvular type will close when the tube is removed without the necessity of a second operation. The intestine will empty itself of its toxic contents through the enterostomy, and irrigation with sodium bicarbonate can also be carried out.

This is the easiest and safest procedure to adopt when the patient is in a poor condition. It is often a life-saving measure and will tide the patient over an apparently hopeless condition. After the intestine has emptied itself through the tube the lumen of the bowel is usually restored and the contents begin to pass normally. The tube can then be removed and the fistula will close spontaneously.

Ileus Duplex.

Sampson Handley has described under the name of ileus duplex a condition where there is paralysis of the bowel below the level of the pelvic brim—that is, in the lower coils of the ileum and the terminal portion of the colon. He recommends as treatment for this condition short-circuiting of the ileum by a jejuno-colostomy with drainage of the large bowel by a cæcostomy. This operation would appear rather severe in a patient whose condition is desperate. Enterostomy is a quicker and simpler operation and can readily be performed by any surgeon with far less strain on the patient.

Mechanical Ileus.

Patients may develop symptoms of intestinal obstruction any time after the tenth day following operation. At this period the obstruction is due to fixation of the bowel by adhesions, and an operation to separate the adhesions and free the bowel will always be necessary. If it is thought desirable, an

enterostomy may be added to drain the bowel for a few days. The outlook in such cases is fairly good provided that operation has not been unduly delayed.

Anti-gas Serum.—It has been suggested that the severe toxæmia of acute ileus is due to the presence of the toxins of the *B. welchii* in the fæcal contents of the bowel above the site of obstruction, the absorption of this toxin by the damaged mucosa leading to the grave general condition of the patient. The symptoms certainly resemble those seen in cases of gas gangrene. The natural outcome of this suggestion was the administration of anti-gas serum to patients, and this has been tried by B. W. Williams[1] during the past two years with encouraging results and noteworthy reduction in the mortality-rate. A prophylactic injection of serum before operation may lead to still better results. The initial dose of serum should be 80 c.cm. given intramuscularly, and later 40–80 c.cm. should be given daily intramuscularly until the bowels are acting effectually.

Administration of Bile.—More recently R. St. L. Brockman[2] has suggested that the symptoms which develop in cases of intestinal obstruction are for the most part due to the prevention of the passage of the bile along the alimentary canal. The administration of bile by the rectum has given encouraging results, the vomiting and toxæmia being diminished in some cases. The dose given was human bile 2 oz. in 4 oz. saline per rectum every four hours and relief was almost immediate. The toxic symptoms may be further controlled by the use of hypertonic saline given intravenously. A quart of 3 per cent. saline given before and again after operation gives favourable results.

Spinal Anæsthesia.—Spinal anæsthesia may be regarded as a valuable alternative to general anæsthesia in cases of intestinal obstruction. This anæsthetic gives perfect relaxation and allows manipulation of the distended coils of bowel to be carried out with great ease. Not infrequently, after the injection of a spinal anæsthetic, the bowels act spontaneously on the operating table, and such injections have been suggested as a line of treatment in cases of paralytic ileus.

Preventive Treatment.

With the practice of earlier operation for acute appendicitis the number of cases where post-operative ileus arises is likely to decrease. This probability is sufficient reason for immediate operation in acute appendicitis as soon as the diagnosis is clear. If the appendix can be removed before it has perforated ileus will not arise. The avoidance of a drainage-tube is an important factor in preventing the formation of post-operative adhesions, for intestinal obstruction is far more common when a drainage-tube has been used. In some cases of acute appendicitis the presence of ileus may be recognised before or actually at the time of operation, and for this reason an adequate incision is necessary to enable the lower ileum to be inspected. For this purpose either the paramedian or the Battle incision is to be recommended. After the appendix has been dealt with the condition of the ileum is examined. If it is fixed by recent adhesions it is gently freed and its mobility restored. Where the gut appears inflamed, sodden and apparently paralysed, either an enterostomy or ileo-colostomy and cæcostomy as advised by Handley should be performed. The early administration of purgatives should be avoided after operation for acute appendicitis. In the treatment of strangulated intestine following hernia operations, a lateral anastomosis to short-circuit the damaged loop is often a valuable procedure where the condition of the bowel is doubtful. Finally, a further cause of ileus after abdominal operation is the over-purgation of patients prior to operation, and the use of castor oil, which causes severe intestinal irritation, should be avoided.

A. H. SOUTHAM, M.D., M.Ch. Oxf., F.R.C.S. Eng.,
Hon. Assistant Surgeon, Salford Royal Hospital; Assistant Surgical Officer, Manchester Royal Infirmary; Lecturer in Operative Surgery, Manchester University.

Special Articles.

OBSERVATIONS CONCERNING THE PRESERVATION OF LIFE IN SHIPWRECKED INDIVIDUALS.

BY J. ARGYLL CAMPBELL, M.D., D.Sc. EDIN.,
AND
LEONARD HILL, M.B. LOND., F.R.S.
(*From the National Institute for Medical Research.*)

A FEW years ago (1923)[1] we advised the wearing of thin mackintosh or rubber "overalls" for shipwrecked individuals, to keep out wind and water whilst sitting on rafts or in lifeboats, and thus prevent excessive loss of body heat by chilling. As a consequence of our observations special rubber "overalls" have been designed for this purpose, and we have employed the suit termed the "warmalonga"[2] in some further experiments. This suit is complete in one piece, and may be readily slipped on and fixed in position. It is not absolutely water-tight, since it has four openings near the feet and wrists to allow water to escape readily, and thus prevent over-cooling of the feet and arms whilst sitting on a raft or in a lifeboat after immersion in the sea. This suit is probably ideal for a person sitting on a raft or in a lifeboat and exposed to wind and splashings. Our present observations were undertaken to determine whether such a non-water-tight suit possesses any advantage towards preserving body heat over ordinary warm woollen clothing when the subject is wholly immersed in water. Our results indicate that such a non-water-tight rubber suit is not obviously superior to ordinary warm clothing for preservation of body heat when the subject is fully immersed in water.

The Plan of Research.

Our plan of research was as follows. The subject, a diver of experience, sat quietly on a chair for about 20 minutes wearing ordinary clothes or special clothes for the experiment. At the end of 20 minutes his heat loss was estimated, usually over a period of 10 minutes, from the oxygen consumption determined by Douglas and Haldane's technique, as recommended by Cathcart.[3] These results formed the base-line for comparison of the effects of immersion in a bath under different conditions as regards clothing. The temperature of the bath was kept at about 22–23° C. The subject lay as quietly as possible in the bath, any movement being due to shivering and quite involuntary. Two experiments (1 and 2) were carried out in which the subject was naked in the bath. In from five to ten minutes he was shivering so badly that the experiment was terminated. Of course, had he been allowed to move—e.g., make swimming movements—he would not have shivered so soon nor so violently. The shivering caused an average increase in oxygen consumption of over 150 per cent., and was accompanied by heat loss of over 160 per cent. (see table). In the next experiment (3) he wore ordinary clothing whilst lying in the water for ten minutes, and the clothes markedly reduced the heat loss due to cooling by the water. Now the increase in heat loss due to ten minutes immersion was only 57 per cent. instead of over 150 per cent. for a shorter period when naked. In Expt. 4, in addition to ordinary clothing, he wore also the rubber suit whilst in the water. Here, again, the clothes protected to a considerable extent, the increase in heat loss due to the water being only about

[1] Medical Research Council Special Report Series, No. 73, p. 179.
[2] Made by Messrs. Siebe Gorman, Westminster Bridge-road, London.
[3] Jour. Roy. Army Med. Corps, 1918, xxxi., 339.

65 per cent. during ten minutes, as compared with 150 per cent. when naked. It will be noted, however, that the addition of the non-water-tight rubber suit did not prevent loss of body heat any more effectively than did ordinary clothing alone, because the water had entered the rubber suit, through the openings at the feet, and replaced the air inside; this occurred soon after the subject entered the water and was facilitated by an assistant pressing on the suit so that the subject sank in the water in the bath.

Various other arrangements of clothing were tested, including the very thick woollen jerseys, long pants, and stockings as used by divers; sometimes two sets of such garments were worn. In these experiments (5 to 13) the subject lay quietly in the bath for about 20 minutes and could have remained longer. Usually he shivered about four minutes after entering the water, but this shivering lasted only a few minutes and was not violent. The heat loss was estimated during the last eight to ten minutes of immersion—

3	11.53 to 12.5	19·0	—	72	0·786	345	—	—	1·65	—	—	Sitting on chair; ordinary light clothing as in Expt. 1.
	12.15 to 12.25	19·0	22·5	87	0·752	547	+202	+58	2·59	+0·94	+57	Lying in bath for 10 mins. in same clothes as above.
4	11.36 to 11.47½	20·5	—	80	0·926	313	—	—	1·55	—	—	Sitting on chair; ordinary light clothing as in Expt. 1, plus rubber suit.
	12.1 to 12.10	20·5	23·0	72	0·835	528	+215	+68	2·56	+1·01	+65	Lying in bath for 10 mins. in same clothes and rubber suit as above.
5	12.10 to 12.20	18·0	—	80	0·763	292	—	—	1·39	—	—	Sitting on chair; ordinary light clothing, plus rubber suit, as in Expt. 4.
	12.32 to 12.42	18·0	22·5	80	0·777	512	+220	+75	2·44	+1·05	+75	Lying in bath for 20 mins. in same clothes and rubber suit as above; temp. inside rubber suit 24–25°C. Shivering after 4 mins., but stopped in another 4 mins.
6	11.50 to 12.0	18·0	—	84	0·800	307	—	—	1·47	—	—	Sitting on chair; same clothes, &c., as in Expt. 5.
	12.10 to 12.19	18·0	22·0	93	0·868	655	+348	+113	3·20	+1·73	+117	Lying in bath for 18 mins. in same clothes as above; shivering after 3½ mins.
7	12.18 to 12.28	21·0	—	72	0·700	275	—	—	1·28	—	—	Sitting on chair; same clothes as in Expt. 1, except no coat; wearing also diver's woollen jersey and pants.
	12.38 to 12.46	21·0	22·5	84	0·843	564	+289	+105	2·74	+1·46	+114	Lying in bath for 15 mins. in same clothing as above; shivered after 4 mins.; shivering gradually lessened.
8	12.13 to 12.23	19·5	—	77	0·700	301	—	—	1·41	—	—	Sitting on chair; same clothes as in Expt. 7, plus rubber suit.
	12.35 to 12.45	19·5	22·5	72	0·766	382	+81	+27	1·82	+0·41	+29	Lying in bath for 20 mins. in same clothing, &c., as above; shivered at about eighth min., but stopped in a few minutes.
9	11.43 to 11.53	20·5	—	77	0·700	310	—	—	1·45	—	—	Sitting on chair; 2 diver's jerseys, 2 diver's pants, and pair thick woollen stockings.
	12.4 to 12.14	20·5	22·5	75	0·837	450	+140	+45	2·18	+0·73	+50	Lying in bath for 20 mins. in same clothing as above; shivered in 4 mins., but stopped in another 3 mins.
10	11.47 to 11.57	18·5	—	84	0·744	306	—	—	1·45	—	—	Sitting on chair; same clothes as in Expt. 9, plus rubber suit.
	12.9 to 12.19	18·5	22·5	79	0·768	484	+178	+58	2·30	+0·85	+58	Lying in bath for 20 mins. in same clothing, &c., as above; very slight shivering.
11	11.49 to 11.59	18·0	—	78	0·766	294	—	—	1·40	—	—	Sitting on chair; diver's jersey, diver's pants, and pair thick woollen stockings, plus rubber suit.
	12.14 to 12.24	18·0	22·5	78	0·824	499	+205	+69	2·41	+1·01	+72	Lying in bath for 20 mins. in same clothing, &c., as above; water at 43° C. poured into suit previously.
12	11.36 to 11.46	19·5	—	77	0·738	304	—	—	1·44	—	—	Sitting on chair; same clothes as in Expt. 11.
	12.1 to 12.11	19·5	22·5	83	0·764	543	+239	+78	2·58	+1·14	+79	Lying in bath for 20 mins. in same clothing as above; shivered after 5 mins., but only for a few minutes.
13	11.48 to 11.58	18·5	—	84	0·746	295	—	—	1·40	—	—	Sitting on chair; same clothes as in Expt. 11.
	11.59 to 12.9	18·5	22·5	75	0·801	484	+189	+64	2·32	0·92	+66	Lying in bath for 20 mins. in same clothing as above; shivered after 4 mins., but shivering lasted only 3 mins.

that is, from about the tenth to twentieth minute. The thick woollen diver's clothing was a good protective against chilling, particularly when worn double, as in Expt. 9; here, after 20 minutes immersion, the heat loss was increased only by about 50 per cent. In Expt. 10, when the non-water-tight rubber suit was used in addition, the heat loss was increased by about the same amount—namely, 58 per cent. In Expt. 8 the rubber suit seemed to reduce the heat loss markedly when compared with Expt. 7, probably because, for some unknown reason, the clothes remained drier in Expt. 8 and contained more air than usual. Whatever the explanation, this apparently protective effect of the rubber suit could not be confirmed by other experiments, the main conclusion being that when fully immersed in water, a subject is nearly as well protected against cold by ordinary woollen garments as he is when wearing in addition a non-water-tight rubber suit as the outer garment. In Expt. 11 hot water at 43° C. was poured into the rubber suit, but this preliminary warming had no material effect on the subsequent cooling by the bath.

Conclusion.

Of course, the ideal for a person immersed in cold water would be warm clothing, together with a water-tight suit which would keep out the water entirely. Our experiments prove, however, that for at least 20 minutes ordinary thick warm clothing affords quite a good protection from chilling, even if the subject does not increase his heat production greatly by movement. This is of importance in connexion with diving at shallow depths for short periods and using the self-contained diver's apparatus, in which the diver carries his own oxygen in a cylinder on his back. Once, however, a person is sitting on a raft or in a lifeboat, exposed to a chilling wind and splashings of water, then the non-water-tight rubber suit would afford very much greater protection from chilling than would ordinary clothing; of course, any ordinary mackintosh material or garment equally impermeable to wind and splashings would be equally effective as the rubber "overalls."

REGISTRATION OF OPTICAL PRACTITIONERS.

REPORT OF THE DEPARTMENTAL COMMITTEE.

THE Committee appointed in March of last year by the Minister of Health and the Secretary of State for Scotland to consider the Optical Practitioners (Registration) Bill and to make recommendations has brought in a report, which may be obtained from H.M. Stationery Office (Cmd. 2999) for 6*d*.

The membership of the Committee consisted of Mr. F. B. Merriman, K.C., M.P. (Chairman), Mr. O. Aves, Mr. W. B. Barker, Dr. H. B. Brackenbury, Mr. L. G. Brock, Mr. E. Treacher Collins, F.R.C.S., Mrs. W. L. Courtney, Lord Cozens-Hardy, Mr. R. J. Davies, M.P., Mr. H. L. F. Fraser, LL.B., Dr. C. O. Hawthorne, Mr. G. E. Houghton, Sir Henry Keith, with Mr. J. S. Henderson (Ministry of Health) as secretary.

The proceedings were held in private, no reports being issued to the press. Oral evidence was taken at 10 of the 14 meetings of the Committee from bodies and persons as follows: Joint Council of Qualified Opticians, Institute of Ophthalmic Opticians, British Optical Association, Association of Dispensing Opticians, National Association of Opticians, the Worshipful Company of Spectacle Makers, Institute of Chemist Opticians, the Association of the College of Optics, Northampton Polytechnic Institute, the General Medical Council, the British Medical Association, Council of British Ophthalmologists, the Medical Practitioners' Union, Ophthalmic Benefit Committee, National Conference of Industrial Assurance Approved Societies, National Conference of Friendly Societies, and the Parliamentary Committee of the Coöperative Congress. Among the memoranda submitted was one from the Ministry of Health regarding optical laws in other parts of the British Empire and in the United States of America.

Previous Inquiries.

It is recalled in the report that although a "Sight Testing Opticians Bill" was introduced in the House of Lords in 1906, and Acts were passed in the following years for the purpose of regulating the practice of sight-testing in Canada, Australia, and the United States of America, the demand for State registration of opticians does not appear to have been pressed strongly in this country until after the war. In recent years the question has become one of increasing controversy and was examined by the Departmental Committee on the Causes and Prevention of Blindness, which reported in 1922 to the effect—

that it would be undesirable and a positive danger to the public for Parliament to pass any measure which might convey the idea that an optician, who is a person qualified to provide glasses prescribed by medical men, is further himself competent to examine the eyes of patients and to *prescribe* glasses for the correction of errors of refraction.

This committee considered that if a register were established it would probably be difficult to prevent unscrupulous persons who might succeed in obtaining admission to it from posing and advertising themselves as experts competent to treat diseases of the eye, and the danger to the public would be increased as they would regard the register as an official guarantee that those whose names were included in it were competent not only to provide but to prescribe glasses, and generally to deal with defects of vision from whatever cause arising.

The Royal Commission on National Health Insurance had the question of the State registration of opticians before them in connexion with their examination of the problems arising out of the provision of ophthalmic benefit which is an additional benefit that may be adopted by approved societies. Without expressing any opinion on the subject, the Commission called attention in their report (1926) to the fact that an ophthalmic service was only part of a general service of specialists and consultants and to the difficulties which were encountered when the State found it necessary to limit the practice of dentistry and midwifery to those possessing the requisite professional qualifications, and said that it was a matter for consideration whether similar problems were not being engendered in the case of the opticians. They pointed out that the difficulties became greater as the volume of unqualified practice increased, and suggested that if it became necessary to regulate the practice of opticians much was to be gained by taking the necessary step while the problem was still manageable.

Arrangements for Ophthalmic Benefit.

It is, states the report, within the discretion of an approved society to decide whether a member, who has been recommended for ophthalmic benefit by his insurance doctor, should be sent for examination to an oculist—i.e., a qualified medical practitioner who has made a special study of the treatment of the eye, or to an optician. If it is decided that the member should be examined by an oculist, the society would normally send him to one of the doctors on a list prepared by the British Medical Association with the approval of the Minister of Health and the Scottish Board of Health. That list contains the names of about 800 oculists practising at some 1000 addresses throughout Great Britain, who are willing to make examinations for approved societies at the special fee of £1 1*s*. It has been reported to the Committee, however, that in the case of one group of approved societies, representing a total of about 6,000,000 insured persons, only a very small percentage of their members recommended for ophthalmic benefit are sent either in the first place or after examination by opticians to oculists, and that this group is satisfied with the services rendered by the selected opticians. These societies make it a condition of grant that their members should go to an optician on the register

prepared by the Joint Council of Qualified Opticians, the fee for examination being 5*s*. The Committee was told also that while some other societies require or recommend their members to go to opticians on the Joint Council register, certain other societies make arrangements for the examination of their members by opticians. In 1924 the sum of about £30,000 was spent in England on ophthalmic benefit, and in 1926 the Joint Council of Qualified Opticians received, for distribution amongst opticians on their register, a total sum of £82,257 out of the funds available for ophthalmic benefit, while during the first part of the year 1927 the corresponding payments to these opticians have been at the annual rate of about £178,000.

Registration in Other Countries.

Provision is made by law for the registration of opticians in eight of the provinces of Canada, in three of the States of Australia, in Jamaica, and in the great majority of the United States of America. The practice of sight-testing is restricted to medical practitioners and to persons whose names appear on the official register, and in addition, in some States, the mere selling of spectacles by unregistered persons is also prohibited. Further, in most cases one of the objects of legislation has been to prohibit the selling of spectacles by itinerant vendors. Generally speaking, opticians in these countries are restricted in their practice to the measurement of errors of refraction, and are prohibited from using drugs or from attempting the treatment of any disease of the eye. This legislation has been effective in putting down the unregulated sale of spectacles, and has had the effect of raising the standard of qualification of opticians.

The Present Bill.

The Bill, of which the main provisions were set out in THE LANCET of March 12th, 1927 (p. 570), is not prohibitive in the sense that it would exclude unregistered opticians from continuing to practise, as is the case in most of the other countries to which our attention has been called. It proposes to leave to a board the duty of deciding the qualifications which would entitle an optician to be placed on the register, and, theoretically at least, it would be possible for a great number of existing opticians to be refused admission to any register which might be set up under the Bill. The Bill has been promoted by the Joint Council of Qualified Opticians, which is an association with limited liability registered under the Companies Acts, and governed by a small committee, the members of which are partly appointed by two other associations and partly elected by the opticians whose names appear on the register of the Council. Before an optician can be accepted for inclusion in the register, he must have obtained the diploma either of the Spectacle Makers Company or of the British Optical Association.

CONCLUSIONS OF THE MAJORITY REPORT.

The conclusions reached by ten members of the Committee, including the chairman and the three medical members, are thus summarised. We have seen, they say, that the functions of even the best qualified opticians should be restricted to the use of mechanical means for the correction of errors of vision, and that in the best interests of the patient the responsibility for any examination of the eyes should be upon an oculist, who, in addition to having access to all the resources of the skilled optician, can bring to bear the whole of his medical experience either in deciding that it is possible to determine the absence of disease or, on the other hand, to recognise and to treat any diseased condition that may be present. Opticians cannot, therefore, provide more than at best a partial service, but in view of the fact that large sections of the community in present circumstances do not avail themselves of the services of oculists and of the fact that the public are not in a position to recognise which are the most competent opticians, there is a prima facie case for setting up a State register in order to produce some sort of order out of the present chaos.

As, however, a considerable proportion of cases of defective vision are not cases of mere refractive error but require treatment other than, or in addition to, the provision of spectacles, it follows that the very prescription of spectacles involves an implied decision that no other treatment is required; and we think that this consideration must necessarily govern the standard to be set for admission to any register. After a careful review of the facts regarding the training of opticians as a whole, we have been forced to the conclusion that it would not be in the public interest to set up a prohibitive register which would involve the admission of practically all opticians who were able to show that they have been conducting bona fide businesses. At the same time the setting up of a non-prohibitive register would be useless if not dangerous unless it were made a condition of entry that every candidate should prove to the satisfaction of the Board his ability to exclude the possibility of the existence of disease before prescribing spectacles. We are not satisfied that even those opticians who are most highly qualified in all other respects are sufficiently trained in this respect. Further, the setting up of a register of sight-testing opticians would necessitate the separate registration of opticians who undertake dispensing only.

We find that it would be necessary not only to impose restrictions on registered opticians in the way of treatment, of advertising, and of using confusing or misleading titles, but that it is imperative that they should be prohibited from using drugs. Such a restriction would in effect severely limit the classes of patients whom the opticians would be capable of treating.

State Register Not in Itself Desirable.

In view of all this, we are convinced that the setting up of a State register of sight-testing opticians is not in itself a desirable policy. There remains, however, the question whether it is nevertheless necessary, having regard to existing circumstances, to adopt this expedient in the public interest. In our opinion the answer to this question depends on how far the medical profession is likely to be able to make the services of oculists available for persons in those sections of the community for whom at present they are, for economic reasons, not available.

Prospect of the Extension of the Services of Oculists.

Whether it is as the result of the establishment by approved societies of ophthalmic benefit, or of the question of registration becoming acute, or of the increasing competition of better trained opticians, or merely of the greater public recognition of the importance of defects of vision, we are satisfied that there exists a movement on the part of the medical profession to provide treatment by oculists on terms which will make that treatment much more readily accessible to the public. We are assured, for example, that so far as insured persons are concerned, negotiations are at present being conducted by the British Medical Association with a view to the establishment in all the more populous districts of clinics or other schemes by which the services of oculists would be made available at fees within the reach of approved societies, having regard to the limited funds available for ophthalmic benefit.

Number of Oculists Available.

Moreover, we are satisfied that in recent years an increasing number of medical men, and particularly the younger men, have been making a special study of ophthalmology; also, that there is good reason to believe that a supply of oculists, sufficiently well distributed to meet reasonable demands, will be forthcoming. The setting up of a State register of opticians would not encourage and might indeed retard these movements. We feel that it would be a retrograde step on the part of the State to do anything to discourage the provision of the best

form of treatment for the greatest possible number of patients.

Future of Opticians.

It has been claimed, probably with truth, that the setting up of a State register would incite those responsible for the training of opticians to raise the standard of qualifications, but we see no reason why the improvement in methods of training which has been made in the last 10 or 15 years should not be maintained, though no register is set up. Whether the register is set up or not we feel sure that numbers of the population will resort to opticians in the future, as they have done in the past, and we think that the natural competition which will be engendered by the movement on the part of the medical profession to which we have referred will have the effect of raising the standard in both classes of practice. Further, in view of the large numbers of opticians who are undoubtedly capable refractionists, we consider it would be beneficial in the public interest if use could be made of their services in that capacity in collaboration with and under the control of oculists.

While we have been forced to conclude that it is not in the public interest that a State register of opticians should be set up, we desire to emphasise that one of the principal reasons on which we base this opinion is our view that it is possible and probable that the medical profession will be able to provide insured persons entitled to ophthalmic benefit with the services of oculists at an early date, and at fees within the limit of the funds from time to time available to approved societies for this purpose. We hope, also, that such a service will be extended to the non-insured population. If, however, for any reason, these hopes are not fulfilled within a reasonable time we do not wish our report to preclude the possibility of a reconsideration of the question in the light of the circumstances then existing.

MINORITY REPORTS.

Of the two minority reports the former is signed by three members, Messrs. Aves, Barker, and Houghton, who conclude that the case for the regulation of the practice of optometry by means of a State register is well supported, and that the Committee incurs a serious responsibility in making an indeterminate report. If this issue is shelved at this juncture through reluctance to tackle the problem they foresee as a consequence—

(*a*) the creation of further vested interests which will complicate the problem on the inevitable reopening of the question;

(*b*) the creation of an unfair prejudice against the case of the qualified opticians whose past voluntary efforts have earned the praise of the whole Committee that has heard the evidence; and above all

(*c*) an encouragement to the pretensions of incompetent persons whose activities constitute the most serious and obvious danger to the public.

In the second minority report Mr. Davies records his opinion that optical practitioners should be registered on the general lines of the provisions of the Bill with the following reservations:—

(*a*) As a great deal of the work of optical practitioners is now performed in connexion with the supply of appliances to members of approved societies, there ought to be at least two representatives on the Registration Board representing what may be termed the consumers, to safeguard the interests of insured persons against any tendency to excessive charges by optical practitioners.

(*b*) The entry of young persons into the profession should not be confined in all cases to those who have passed the matriculation certificate, so that suitable young aspirants whose means have precluded a matriculation standard of education should be enabled (with maintenance allowances) to train and qualify for the profession.

The register on its first compilation should, he thinks, include, in addition to those of undoubted qualification and training, a limited number of those with a wide experience of sight-testing and the sale of appliances, but who are now without other qualifications. There should, however, be a time limit (say, as from Jan. 1st, 1930) to the operation of this principle.

CANCER OF THE UTERUS.

THE REDUCTION OF MORTALITY.

THE Ministry of Health to-day issues the sixth[1] of a series of memoranda compiled by the Departmental Committee on Cancer. These memoranda are based on a statistical analysis of the records of all the series of patients affected at such sites which have been published in the medical journals of the world, supplemented, when practicable, by an examination of the records of representative hospitals at home. Such analysis shows the effect of current methods of treatment and affords a standard of comparison for the future. The report is an instructive statement of our present knowledge and its implications, as will be seen from what follows.

ABSTRACT OF THE REPORT.

Cancer of the uterus accounts for between one-fifth and one-sixth of the total mortality from cancer among women. It may occur at any period of adult life, and does so with steadily increasing frequency until at least the age of 60 to 65, after which a small decrease is recorded. Among single women the recorded increase continues to higher ages still. There is therefore no special tendency for the disease to occur about the period of the menopause. Cancer of the cervix is perhaps ten times as common as cancer of the body of the uterus. It is more serious and affects on the average younger women, and the following statements should be regarded as applying to it.

The commonest *symptoms* are hæmorrhage, discharge, and pain. Hæmorrhage occurs in nearly 70 per cent. of cases—especially irregular hæmorrhage, though increasing excessive loss at the monthly periods may also be a manifestation. Irregular periodicity is not uncommon arising out of the menopause alone. The important point to bear in mind therefore is that irregular bleeding in a woman of any age should necessitate immediate and thorough investigation of its cause. The next commonest symptom (in about 20 per cent. of cases) is an abnormal discharge; less common still, at all events in the early and curable stages, is pain (in about 8 per cent. of cases). In the absence of treatment the disease runs its course, from the onset of symptoms to death in a period which, on the average, does not extend to two years, and may be put at one year and nine months. This period, known as the "natural duration," is considerably shorter than that for cancer of the breast.

Antecedent Conditions.—In many instances the disease supervenes upon a chronic inflammatory condition which is often the result of an injury arising from childbirth, and may or may not be associated with a microbic infection. This sequence of events is no more common among women who have borne many children than it is among those who have borne few. It appears, therefore, that it is not a question of the number of labours but rather the fact of a labour having taken place at all that is of importance in causation. A proportion of cases, however, occurs among infertile married and among single women, while a few cases have been recorded in virgins.

Diagnosis.—Once suspicion has been aroused by one or more of the three main symptoms an immediate local examination is essential. In no other way can the point be settled and a sure diagnosis, whether negative or positive, be arrived at. Women having such symptoms should allow no consideration to interfere with their determination to undergo any examination necessary for reaching a definite diagnosis.

Treatment.

Until recent years treatment consisted of operation for those patients seen at a sufficiently early stage,

[1] Cancer—VI. Circular 826. Ministry of Health, 1928. H.M. Stationery Office. 1*d*.

and palliative methods for the remainder. Nowadays the position is changing owing to the gradual advances in treatment by radiology. In some foreign hospital centres this method of treatment has already replaced operative methods entirely; in other centres and countries operative methods are employed for the earlier cases, and radiological ones for those deemed imoperable or unlikely to survive operation for a prolonged period.

Operation.—In judging the effect of operative treatment three main factors require consideration—operability, operative mortality, and survival-rate. (1) Operability varies to some extent with the skill and judgment of the surgeon, but on the average less than half the women applying for treatment are in a condition at which operation can reasonably be undertaken. (2) Operative mortality cannot be considered alone, but only in conjunction with operability. Bearing in mind the varying factors it may be said that on the average the operative mortality is in the region of 10 to 20 per cent. Although of recent years mortality after operation has declined, especially in the hands of experienced surgeons, it still remains an important factor in advanced cases. (3) If recurrence of the local disease takes place after operation, it does so in at least 90 per cent. of cases within five years of the operation. This generalisation is sufficiently true to render survival to a period of five years a reliable criterion of the results of operation. The proportion of patients surviving for five years after the modern operation may be put, on the average, at 40 per cent., though the ratio naturally varies with the skill of the surgeon and the stage of the disease at operation. The results in early cases are roughly twice as favourable as those obtained in patients on the borderline of inoperability.

Radiation.—Treatment mortality is almost negligible with modern radiological methods, a point of distinct importance in a comparison with operative treatment. In weighing results two classes of patient must be considered, the operable and inoperable, since both are susceptible of treatment by radiation. As the method is modern and incompletely developed, making use of agents whose action is not yet well understood, it was applied in the first instance to patients beyond the reach of surgical operation. The period during which observation of cases has been possible is short, some 12 to 14 years, though long enough to indicate that in about 10 or 12 per cent. of these so-called inoperable cases survival to a period of five years can be secured. Some radiologists have extended their treatment to patients in the operable class with the result of obtaining a survival-rate to five years approximately the same as that secured by operation—viz., 40 per cent. These results are secured at the cost of practically no immediate danger to life and without some of the other disadvantages attendant upon surgical operation; moreover, in those instances where eradication of the disease is not secured a considerable degree of palliative action is possible.

A summary account such as the above may, however, convey a misleading impression, since in England the methods have not been extensively used and the published results are very few. The material and apparatus necessary for the treatment are costly, the action of the agents is very incompletely understood, and the number of centres equipped with the necessary material, apparatus, trained staff, and beds is so far small. Pending further developments, therefore, in this and possibly other methods of treatment, chief reliance must be placed on operative surgery.

Conclusions.

A steady improvement in the treatment of local lesions incidental to childbirth may reduce the *incidence* of cancer of the cervix and so accelerate the present downward trend of mortality at this site. Since the interval between the initial lesion and the onset of cancer may be 10, 20, or even 30 years, and since, probably, a small proportion only of women with such lesions eventually develop cancer, the evidence of such preventive treatment will be delayed and gradual in its appearance.

From the point of view of the surgeon or radiologist improvements in treatment depend upon future advances in medical knowledge. From the patient's point of view immediate improvement is possible through a larger proportion of patients presenting themselves for treatment in the early stages of the disease. In spite of the advanced stage of the disease at which women now present themselves, as shown by the low proportion found suitable for operation, as many as 40 per cent. of those undergoing operation survive for five years—and recurrence after five years' freedom is a comparatively rare event. The future holds out promise of an equally effective and, it is permissible to hope, an even more effective treatment by radiology without some of the dangers and inconveniences attendant upon operation.

As has been said, the average interval between the onset of symptoms and death in untreated patients is less than two years. On the average, some six months is allowed to elapse between the patient's noticing symptoms and applying for treatment at hospital, and it is clear that one great cause of the comparatively small proportion of cures is delay in seeking treatment. When it is also realised that by no means all the sufferers apply for treatment, and that among those who do the results are twice as good in early cases as in late ones, some idea is reached of the number of lives that could be saved if *all* sufferers underwent treatment at an early stage. Women should be helped to realise that *irregular* bleeding from the womb imperatively demands immediate and thorough investigation. The mere possession of this knowledge, however, may not be sufficient, since for various reasons, such as difficulty of access to hospital, interference with domestic duties by delay at hospital, unwillingness to submit to operation, a natural human tendency to procrastination, &c., women may fail to act upon the knowledge. Educational measures may be confidently anticipated to be of value, whilst investigation of the causes of delay in obtaining early treatment and their remedy or removal whenever possible should also be helpful. One of the ways by which some causes for delay may be counteracted is now undergoing trial by certain local authorities—namely, the establishment of a special centre or "clinic" for diagnosis and advice. In this, and doubtless in other ways, means may be found for inducing a larger proportion of patients to undergo treatment at a stage where the prospect is hopeful. The means for effective treatment exist; the problem is that of bringing the patients within their sphere.

(FROM OUR OWN CORRESPONDENT.)

Tuberculosis among School-children.

THE School Board of Vienna, in coöperation with the Municipal Board of Health, some time ago started regular medical examination of all children attending public or private schools. Each of the school doctors has to examine about 2000 children several times annually. Within the last two years special attention has been paid to the incidence of tuberculosis, and besides a clinical examination, tests have been made by rubbing a small quantity of "dermotubin" into the skin of the forearm or the breast. In the school year 1925–26, 33·7 per cent. of the boys and 34·5 per cent. of the girls gave a positive reaction, whilst in 1926–27 the figures were only 30 per cent. for the boys and 31 per cent. for the girls. In cases reacting severely or showing progressive symptoms, the members of the family were asked to come up for examination at one of the tuberculosis stations in Vienna. Nearly 80 per cent. responded, and it was thus possible to ascertain the state of their health. Thirty-two per cent. appeared to be healthy—i.e., non-tuberculous—while 68 per cent. were more or

less tuberculous or showed signs of previous lesions. Only 17 per cent. had manifest lesions. It is interesting to note that whilst among the children the incidence was a little greater among females, among adults the male was more often affected (54 per cent.). Of the school-children who were tuberculous, 75 per cent. showed symptoms from the respiratory tract alone, 3 per cent. were affected in other organs as well, and 4·2 had non-respiratory lesions only. The remaining cases could not be definitely classified without a further examination, which was beyond the scope of the school doctor.

Foreign Students.

The medical faculty of Vienna has decided to stop admitting foreign students, other than qualified doctors, to the institute of anatomy and to the dissecting theatres until all Austrian students have been accommodated. This measure has been adopted because of the permanent scarcity of bodies for the dissecting rooms. At present there are only 27 bodies available and not more than 50 others are likely to accumulate during the winter term. Over 600 students are engaged in dissecting, and some 25 bodies are also required for examination purposes. There is, therefore, a real danger that many students may be prevented from completing their studies owing to the impossibility of finishing their course in anatomy. As more than 40 per cent. of the medical students in Vienna are foreigners, mostly from the south-east of Europe and the Balkan States, the Austrians resent their presence. This term all the Austrian applicants had to secure their places a fortnight before the ordinary matriculation took place, and in consequence, a large number of Hungarian, Bulgarian, and Rumanian students have left the university and have gone to Italy, France, and Switzerland, where there are no restrictions of this kind. Several classes of the population deplore the loss of some hundreds of students, and in medical circles, too, the decision of the Senate is criticised. The restrictions are only intended for students and not for doctors, and the usual post-graduate work for foreigners in hospitals and other institutions is not affected.

Surgery of the Brain.

In the course of a recent lecture at Vienna University Prof. Anton v. Eiselsberg said that in cases of head injury active measures should be taken in the presence of any progressive condition such as hæmorrhage from the meningeal artery. Otherwise, a conservative policy might be adopted. Where the brain was injured, he said, the patient usually died unless operation was undertaken. During the war Bárány had operated at once on all tangential injuries of the skull, closing the wound immediately, and this plan had given satisfactory results in hospital. All open injuries of the skull needed active treatment and should therefore be dealt with in hospital as abscess of the brain might follow even a slight wound. Conservative, expectant treatment was useful in injuries of the base and in concussion of the brain. Fracture of the base did not necessarily mean an unfavourable prognosis, and the results were bad only when there was infection from the middle ear or the frontal sinus. Operation would be needed if the intracranial pressure increased. Gunshot wounds of the skull, continued Prof. Eiselsberg, might be either tangential, perforating, or intracranial. In the first group all the injured parts—brain, dura, &c.—should be removed so as to prevent bacteria from finding cover. In perforating wounds, as in gunshot wound of the thorax, the openings at the entrance and exit should be cleared of all useless material; the intermediate tissues could not be disinfected. With intracranial wounds the patient was in constant danger. If possible, bullets lying superficially should be removed, but deep-lying bullets were for the most part best left alone as operation was often very dangerous—even more dangerous than the presence of the bullet. In cases of cerebral abscess, Prof. Eiselsberg said, it was difficult to know when to operate. If no pyogenic membrane had formed, inflammation would continue in spite of the abscess being opened. The surgeon should always try to open and drain the abscess at its deepest point, and the posture of the patient should be adjusted accordingly. If too long a time elapsed before operation the patient might succumb to a pyencephalus. (Ten patients out of 18 operated on for cerebral abscess at his clinic had died from this cause.) The condition called pseudo-abscess, of which he had seen five cases, must also be taken into consideration; in these cases the typical symptoms of an abscess developed after injury, but operation revealed a cyst with clear contents.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Murder by Lead Poisoning.

A REMARKABLE trial took place lately in Landberg, a town in Brandenburg. The case was as follows. A man, after having drunk a glass of beer at home, was taken ill with severe colic. As the symptoms recurred repeatedly a doctor was consulted, who found the patient with a livid complexion and suffering from spasmodic contraction of the intestine, severe constipation which could in no way be overcome, and with retention of urine. His condition grew worse, and he died about a month after the doctor's first visit. Owing to the obscurity of the case it was suggested that a post-mortem examination should be performed, but the wife of the deceased objected, saying that she had promised her husband that she would not allow it. Some time later, however, it was rumoured that the man had not died a natural death and accordingly the corpse was exhumed by judicial order, and an official post-mortem examination was made by the law-court medical officers. The result was very striking. The stomach and the intestines were shown to form a dark mass containing sulphide of lead, which was detected in nearly every organ of the body, the total quantity being 19 g. At the trial the wife finally admitted that she had given her husband a powder which her lover had procured for her. He had designed the powder as a sedative compound, but it obviously contained white lead. Both the wife and her lover were sentenced to death.

Medical Staff on Liners.

Formerly medical officers on liners were usually appointed for a single journey only, the appointment being renewed if both parties agreed. The Hamburg-Amerika Line, the big German shipping company, has now made other arrangements, appointing a staff of permanent medical officers. Medical practice on board ship, they point out, requires special knowledge which cannot be gained by the medical man who only makes one or two journeys with the object of seeing foreign countries or enjoying the life on board. The new permanent medical officers will receive a salary sufficient to enable them to give up private practice, and they will be given regular holidays. The company, moreover, has decided to pay the expenses of post-graduate study for their doctors which will enable them to keep abreast with modern progress. The pharmacies and the hospitals on board ship have also been enlarged and fitted with modern appliances. This information will be of interest to readers of THE LANCET in connexion with the article published on Oct. 29th, 1927, dealing with the medical service of the British mercantile marine.

Aeroplanotherapy.

Dr. Kettner, of Charlottenburg, reports that one of his patients, the owner of an aeroplane, asked him whether he agreed to his daughters aged 9 and 11 being taken a short trip in his aeroplane, in spite of the fact that they were suffering from whooping-cough. He gave his consent, and the result was that after the first journey the coughing fits became less frequent and

considerably less severe. Dr. Kettner thereupon advised the father to repeat the trip, and within a short time the illness was cured. The children remained in the air for about an hour each time and the aeroplane rose to an altitude of 3000 metres. A third child, being only one year old, was not taken with the others, and his illness took the usual course. Dr. Kettner proposes that the large aeroplane works should place aeroplanes at the disposal of the health authorities for experiments on a larger scale. Change of climate is known to be the best remedy against whooping-cough; it may sometimes be much cheaper for patients to travel in an aeroplane than for them to spend weeks in the mountains or at the seaside.

The Action of Hormones.

The German Pharmacological Society lately held its annual meeting at Würzburg. The first subject to be discussed was the physiological action of insulin. Dr. Kessel said that the glycogenic action of the liver is hindered by insulin and the power of the erythrocytes to absorb sugar is increased. Guanidine also produces a decrease of sugar in the blood, but only in a lethal dose. In synthalin, he said, the lethal and the curative doses are not widely separated. Dr. Beylonia (Utrecht) spoke of the action of the hypophysis, of which he considers there are five different parts with different actions. Some of these act on the uterus, some on the bronchial muscles, and some on the breast. Prof. Ernst Laqueur (Amsterdam) spoke on female sexual hormones, of which he had produced an extract acting on sexual desire and on the growth and the secretion of the mammary gland. Prof. Ludwig Fraenkel (Breslau) said that the compound acted successfully in about 30 per cent. of the cases in which there had been trouble caused by weakness in the function of the ovaries, menstruation being again restored. The hormone may be extracted from the urine of women in the last months of pregnancy.

A New Institute at Heidelberg.

An institute for research in internal medicine is to be established in Heidelberg. It will be connected with the existing institute for cancer research, founded by the late Prof. Czerny, and with the institute for the study of albuminous substances, of which the late Prof. Kossel was the head. The new building, for which a committee of medical experts and distinguished men of other professions will be responsible, will include departments for pathology, medical chemistry and physics, and psychology. The city of Heidelberg has presented the committee with a building site, and the German Treasury will contribute to the expenses.

Election to the Medical Chamber.

This year proportional representation, which is employed for political elections throughout Germany, was for the first time used in electing members of the medical chambers which are the official representative bodies in every province, and have disciplinary powers as well as the right to tax members of the profession. Formerly there used to be practically no contests during the elections in Berlin and in the provinces, since large medical unions gave their consent to a list of representatives, an absolute majority being in this way assured. Under the new system in Berlin this year there were very heated contests resembling in many ways political elections. As many as eight lists of candidates were presented to the voters; of these the only ones of interest, apart from the list of the combined medical societies, were those of the Socialist medical men, of the assistants, and of the club medical officers, who are against the system by which patients have free choice of doctor. At least 75 per cent. of the profession took part at the elections, with the result that members on the list of the combined medical societies, who alone had held all the seats in the former chamber, gained only 52 out of a total of 106. The discussions in the chamber are therefore likely to become more animated.

Sick Club v. *Medical Profession.*

The sick club of the Krupp's works at Essen has instituted a dispensary for its members and tried to appoint medical men who alone will have the right of attending to members. As a large part of the population of Essen is employed at Krupp's works, if this came into effect local medical men would be deprived of a serious part of their income. The local branch of the Hartmann-Bund therefore has prohibited its members from accepting appointments at the dispensary, which has thus had to be closed down. The members of the club in consequence have had the greatest difficulty in obtaining medical attendance other than at their own expense, and the club has brought an action for damages against the Hartmann-Bund. This has been dismissed by the court which stated that the action of the Hartmann-Bund was undertaken to protect the local medical profession. The work of the club would not, as the plaintiffs had alleged, be rendered impossible as a result of the boycott ordered by the medical profession, provided that the medical men were not excluded from working at the dispensary.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

The Position of Midwives.

THE present position of midwives in the United States is shown as a result of an inquiry made throughout the country by the Medical Society of Virginia. Out of 96 questionaires sent to State medical societies and health officers 59 replies were received. Only four States, all in the south, reported that the number of physicians was insufficient to attend all cases of labour. Four other States qualified an affirmative answer by adding "if properly distributed." Massachusetts, Vermont, New Hampshire, Michigan, Iowa, Oklahoma, Nevada, and Kansas stated that 95 to 100 per cent. of the indigent or poorer cases were attended by physicians. Delaware, North Dakota, and Colorado estimated 80 to 90 per cent., while all the rest gave figures lower than 50 per cent. As regards the medical sentiment towards midwives 16 States do not want them, 14 do "when they are necessary." Two States want midwives for coloured cases only, two States are indifferent, and two States so hostile they will not recognise them at all.

In New York State, according to *Health News*, the official organ of the Department of Health, regulation of the practice of midwifery is resulting in the gradual disappearance of midwives. When the licensing of midwives was first required in 1914 a survey showed more than 1000 women practising in the State (New York City and Rochester excluded). Some of these had had four years of training in European schools, others had some training, while still others were dirty in their methods, ignorant, and absolutely untrained. All were more or less careless in reporting births. The most disreputable lost their licences forthwith. Since 1914 a total of 773 women have been licensed, but as there is a constant loss of midwives from practice, as is the case in every country, there will be only about 300 licences issued in 1928. Only 11 first licences were issued in 1927. The number of births reported by midwives seems to be decreasing even more rapidly than the number of midwives in practice. In 1916 it was estimated that midwives were reporting 16 per cent. of the births; ten years later only 6 per cent. were reported by midwives.

While this tendency seems to be fairly prevalent throughout the country, leading obstetricians are asking whether it is certain that the American system of giving preference to physicians and hospital care of maternity is really better than the European system, which allows midwives to practise in normal cases. The statistics of maternal morbidity and mortality, even when allowance is made for possible deviation in standards of notification, do not give much comfort to

the United States. Moreover, Dr. Josephine Baker has recently produced comparative statistics from the States themselves which are all in the favour of the midwife, imperfectly trained and supervised as she so often is. This is plainly shown in the following tables derived from Dr. Baker's statistics :—

TABLE I.—*States in which Midwives are Working.*

	Per cent. births reported by midwives.	Maternal mortality.
Minnesota	9·4	5·3
Kentucky	17·7	6·0
Maryland	18·1	5·8
New Jersey	21·7	6·4

TABLE II.—*States in which Midwives are not Working.*

	Per cent. births cared for by physicians.	Maternal mortality.
New Hampshire	100·0	7·1
Vermont	100·0	6·8
Oregon	100·0	7·2
Wyoming	99·2	9·0

The corresponding rate for the birth registration area is 6·4. It is to be observed that the States in Table II. are all sparsely populated. On the other hand, the coloured population of Kentucky and Maryland would stack the cards against the midwives. One argument used by public health officials against the employment of midwives has been that the ideal is to care for all cases of labour in hospitals. Whether or not this ideal is practicable is one question; another is as to whether it is desirable. The increasing number of hospital cases in the country has not so far affected the incidence of puerperal sepsis. Another argument against midwives is the difficulty of finding material on which to train them. This difficulty, however, is probably not insuperable, especially if midwives trained in one State should be admitted to practice in another.

Marriage and Divorce.

Marriages have increased from 1925 to 1926 by 1·2 per cent. and divorces by 3·1 per cent. Reckoning each per 1000 estimated population the marriage-rate has fallen slightly (from 10·30 to 10·26), while the divorce-rate has increased from 1·52 to 1·54. The change for the country as a whole is not great, though in individual States there have been large changes. Thus the marriage-rate in Nebraska has risen by nearly 20 per cent., while the divorce-rate in Florida has increased by more than 25 per cent. In order to determine whether there is any relationship between the changes in marriage and in divorce-rates in the different States I have calculated the correlation coefficient which I find to be $+0{\cdot}26 \pm 0{\cdot}08$—sufficient to indicate that some relationship does exist. Nevada remains the popular resort for divorce with a wholly fictitious rate of 13·19. The highest marriage-rate is 21·6 in Florida, Maryland is second (16·3), and Delaware lowest (4·6).

The Toxicology of Tobacco.

From the digest of medical literature which he prepared recently for the Committee to Study the Tobacco Problem, Prof. Schrumf-Pierron, of Cairo, concludes that "the chief poison in tobacco-plant leaves is nicotine." [1] The more important of the possibly synergic poisons are, in his view, pyridine, ammonia, and collidine. Prussic acid, carbon monoxide, pyrolin, the phenols, &c., "have but a secondary and perhaps negligible effect." Since this summary was prepared two new poisons have been added to the list. In Germany, at the Kaiser Wilhelm Institute for Biochemistry, it has been discovered that there is derived from the plant pectin in tobacco an appreciable quantity of methyl alcohol [2] approximately 40 mg. in 20 cigarettes. In the United States at the North Dakota Agricultural College, Dr. Remington has found arsenic present in various brands of tobacco "in quantities greater than the amount generally permitted by the authorities in food." [3] Perhaps these poisons, too, belong amongst those that have a secondary or negligible effect. Even non-smokers consume moderate quantities of plant pectin (though not in the form of vapour) and the ills usually attributed to excessive smoking are not suggestive of arsenical poisoning. The intestinal symptoms which might be attributed to arsenic are associated rather with acute than chronic tobacco poisoning, and have already been saddled pretty surely on the nicotine content of the tobacco.

Tularæmia.

Warnings now appear with some regularity in the daily papers against the risk of contracting tularæmia in skinning and cutting up rabbits. The rather attractive title of this new disease gives rise to some interesting speculations. I have heard one member of a county medical society with classical leanings derive the "tular" from the Greek. A writer in the *Spencer Reporter* (Iowa) gives it a bacteriological origin. "The germ," he writes, "known to science as the toolaroo, is so slender that it can skate right through the human skin." The more prosaic associate the name of the disease with that of the district—Tulare County in California—where it was first discovered.

The American College of Physical Therapy sails from New York for London on May 26th. Their programme will take them also to Paris, Montreux, Zürich, Vienna, Berlin, and Copenhagen. The International League against Epilepsy sails from New York on March 17th and will also visit London before proceeding on its European tour. The American Psychiatric Association has also plans for a visit to Europe.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Work of the Appointments Commission.

IN the midst of the discontent which has been roused among the members of the local authorities by the working of the Appointments Commission which has displaced the local authorities in regard to the appointment of officers, it is gratifying to read a considered opinion from an independent observer in favour of the working of the new system. In a public speech delivered recently the Bishop of Killaloe used the following words: "These offices are now filled by a detached body appointed so as to be free from the powerful local influences that very often directed appointments in the wrong direction. No doubt this is often disappointing to the local interests concerned; but I think that, on the whole, the people will find in the long run it is the best method, and that they will have the benefit of the very best appointments. The system will help to remove from our public life things that were a great source of corruption and jobbery, if we can believe public rumour, and I am afraid there was too much truth in it. No matter what they were made of, no matter how good their intentions, the local gentlemen on whom the responsibility of making appointments fell were not always free; they were embedded in a network of local connexions which deprived them of their freedom, and I often sympathised with their position. I believe that the new system is to their advantage and to the advantage of the public, though, of course, it may cut rather painfully in some instances."

QUEEN CHARLOTTE'S MATERNAL MORTALITY FUND. In response to the appeal initiated last May for £250,000 to help Queen Charlotte's Maternity Hospital to study the causes and conditions of maternal mortality, a sum of £60,000 has so far been raised.

EXTENSION OF ST. BARTHOLOMEW'S HOSPITAL.—The site of Christ's Hospital, which has been acquired by St. Bartholomew's, has now been cleared, and the new surgical block of 250 beds, with five operating theatres, can now be begun. It will cost £177,000. When means are available the governors intend to erect a block for paying patients at the corner of Little Britain and Smithfield.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH.

A BRIEF SURVEY OF 1926.

OPPORTUNITY was given us during the year that is past to comment on some 120 annual reports dealing with the public health work done in England, Wales, and Scotland in 1926, and an attempt may now be made to summarise a few of the points contained in these reports as an indication of the status of public hygiene.

General Sanitation.

In *housing* matters a slightly more optimistic vein is noticeable, though very few medical officers express themselves satisfied with the rate of progress. In most districts more houses were built in 1926 than in any year since the war. In some areas the natural increase in the population is now being provided for, and in a few something is being done to catch up the arrears of the years before and during the war. It has not been possible to close "unfit" houses to any extent, and little has been done in the matter of slum clearances. There is general agreement that as yet no provision has been made for the poorest class of the community, though in a few cases perhaps there are signs of a general upward movement. The need for cheaper houses is being expressed, and in many cases the amenities of the new municipal houses are spoilt by subletting.

There is a demand for regional planning and for control of the building which is going on along the lines of motor traffic regardless of drainage and water facilities and of æsthetic effect on the beauty of the country side. At the top of the social scale we have the disfiguring effect of week-end bungalows, while at the other end we have the nuisance from dwellers in vans and makeshift homes.

In the northern towns there is a much more determined effort to get rid of privy middens, pail-closets, and the like. Salvage schemes are being added to or replacing destructors. Financial restrictions hamper the perfection of sewage disposal schemes, and many medical officers are becoming despondent about the question of rivers pollution. Research is needed as to better means for dealing with wastes from collieries, paper works, sugar beet factories, &c.

In many counties the question of *water-supply* is a difficulty, and the new legislation with regard to dairy farms has brought the defective nature of our organisation for the equitable distribution of available water into the limelight.

More interest is being taken in the prevention of *atmospheric pollution*, and there is a healthy demand for regional smoke abatement committees, which may help to abolish the absurd permissible limits for black smoke, still obtaining in some of the mill towns.

Clean milk competitions increase in number, and much is hoped from the new Milk and Dairies Act. The production of designated milks makes some progress, but steps are needed to prevent ordinary milk being sold under fancy names. The working of the Tuberculosis Order has been a disappointment, and lacks the preventive point of view, as has been pointed out in our columns[1] by Dr. W. G. Savage. Compensation for bovine tuberculosis has been asked for by the agricultural interests for some 30 years, but sanitarians have always stipulated that it should be coupled with a well-thought-out scheme for reducing the prevalence of the disease. Now, apparently, we have the compensation without the scheme. In Scotland it would seem that better results are being obtained, and most of the counties are arranging for regular veterinary inspection of milk herds.

Infectious Diseases.

Immunisation is being more used for the prevention of diphtheria, for the protection of hospital staffs, and for dealing with outbreaks in residential institutions, and some local authorities are offering this protection to the children in their district. Good results are being claimed for antitoxin in severe cases of scarlet fever. The notified cases of encephalitis lethargica have been fewer than in the previous year, but the deaths proportionately more numerous, owing to deferred fatal results in cases notified in previous years. The establishment of joint special institutions for the survivors serving large areas has been mooted, and will no doubt take more definite shape when further experience has been gained at institutions such as Winchmore Hill.

Tuberculosis dispensaries are being more used for consulting purposes. No new treatment for pulmonary tuberculosis created any favourable impression during the year, but the value of artificial pneumothorax treatment for suitable advanced cases is becoming more generally recognised.

Maternal and Child Welfare.

In many reports it is shown that maternal mortality from childbirth and neonatal mortality have declined little, if at all, since the beginning of the century and antenatal work is usually held out as the remedy. In some cases antenatal advice is given by the health visitor, by the midwife in charge of a municipal maternity home, or by the infant welfare medical officer at a centre, but only in a few districts has this antenatal work developed into real preventive midwifery at antenatal clinics conducted by obstetricians of experience. The issue of the Puerperal Fever Regulations has met with a good response, and in many districts arrangements have been made for the provision of hospital treatment, special nursing in the home, a consultant's opinion, and bacteriological examinations.

The damage done to eyesight by ophthalmia neonatorum grows distinctly less, and most sanitary authorities have complied with the Ministry's suggestion to forgo efforts to recover the fee of the doctor called in by the midwife on account of the condition of the baby's eyes.

Orthopædic schemes for children of pre-school and school age have made decided progress, and more beds are being made available for non-pulmonary tuberculosis. General interest has been aroused in the question of the control of acute rheumatism in childhood, and the attempt to prevent heart disease, resulting in at least two municipal schemes—namely, in Paddington and Kensington—during 1927. Light treatment is being more extensively tried both at infant welfare centres and for tuberculosis. Most districts can claim during the last two decades an extraordinary reduction in infant mortality, apart from that of the first few weeks of life, but the statistics we have given show that for the best results we must not look to health resorts. One would have thought that the best possible advertisement for a health resort would have been low death-rates of mothers and infants. Health resorts cannot, of course, avoid some of their death-rates being swollen by the aged and invalid, who throng to them with the hope of prolonging their lives. This does not apply to the rates mentioned, which are calculated per 1000 births. There may be something in the suggestion made by one medical officer of a health resort that the mothers are too busy catering for visitors to have much time to attend to their own children. It might be pertinent to ask, "Should a health resort ever have a day nursery?"

Administration.

Many of the reports give evidence of progress towards unification of the public medical services with its broadening effect on the work of both the medical and the nursing personnel. Financial considerations have interfered with the increases of staff required to cope with the recognised need for better medical supervision of the pre-school child. The same remark applies to the school dental staff.

[1] THE LANCET, 1927, i., 722.

PUBLIC HEALTH IN THE LOCAL LEGISLATION OF 1927.

A SURVEY of the public health provisions in the Local Acts of Parliament passed in 1927 does not reveal many notable new developments. The Fleetwood Urban District Council has taken precautions to control the preparation of prawns and shrimps for sale. Every dealer in prawns and shrimps within the council's district who contracts with an employee or any other person for their preparation for sale for human food must enter on a special list the name and address of any person so contracting with him or so employed by him otherwise than on his own premises. No shrimps or prawns are to be supplied in pursuance of any such contract or employment until the name and address has been entered on the list, together with the date of delivery. The lists are to be open to inspection by the sanitary inspector. Notice of the new law is to be published locally by newspaper advertisements and handbills. The maximum penalty is fixed at 40*s*. Other instances of food legislation are more familiar. Buxton has prohibited the inflation of meat carcasses. Sunderland has taken precautions against the contamination of food intended for sale. Food poisoning has been made a notifiable disease at Aberdare, High Wycombe, and Swansea. Several local authorities enact penalties upon the original vendors of unsound food and authorise the search of sacks and parcels, carts and other vehicles. Food storage accommodation in dwelling-houses is regulated frequently; so is the manufacture of potted meats and ice-cream; another not uncommon clause is the restriction upon the conduct of a food business by an infected person, and there is also the usual prohibition on the sale or handling of food by a person suffering from tuberculosis. Fleetwood, Buxton, and High Wycombe arrange for compensation to employees who are made to cease work in order to avoid the spread of infectious disease. Other usual provisions against infection are those for closing Sunday schools and restricting entertainments in time of epidemics. Parents, too, are in several cases obliged to notify the head teacher of a child's infection. At Sunderland, Aberdare, and High Wycombe the furnishing of laundrymen's names can be insisted upon. Fleetwood provides for the removal of bodies where death is due to infectious disease; Leeds provides for the removal of infirm and diseased persons. The Liverpool Corporation failed to carry its proposed clause to make venereal disease notifiable, and the Bradford precedent was cited in vain. Fleetwood has arranged for the municipal supply of antidotes to doctors, and both Fleetwood and Sunderland dealt with infectious or parasitic disease in stables. Clauses about dust-bins, offensive trades, slaughter-houses, and the cleansing of filthy persons are nowadays too common to need mention. Attention should, however, perhaps be drawn to the special sanitary legislation of Leeds and West Bridgford. Leeds enacts that, when there is adequate water-supply and sewering, the corporation may serve the owner of a building with a notice requiring existing trough-closets to be converted into water-closets. If the existing trough-closet is not injurious to health and does not amount to a nuisance, the corporation will share the expense. In the case of West Bridgford, the local council may similarly insist on the conversion of slop-closets to water-closets and may require the provision of a separate receptacle for ashes and house refuse.

Public health, of course, is merely one aspect of the authorised statutory activities of local authorities. Those activities range from the provision of municipal golf courses (as at Liverpool) to the maintenance of grave spaces (as at Fleetwood) for a capital sum. The concession to the Bristol Water Company and the Reading Gas Company of power to give their employees the benefit of a recreation-ground is another welcome sign of the times. Other gas, water, and electricity undertakings indicate schemes of profit-sharing. Matlock Urban District Council seems to be the only local authority to consolidate its legislation in 1927, and to substitute a single orderly Act for a series of successive and overlapping enactments. It may be worth while to mention that H.M. Stationery Office publishes an index to the Local and Private Acts of the year, and that the index for 1927 has already been issued at the price of 2*s*.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 24TH, 1927.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 255 (last week 212); scarlet fever, 1751; diphtheria, 1324; enteric fever, 52; pneumonia, 1561; puerperal fever, 35; puerperal pyrexia, 82; cerebro-spinal fever, 10; acute poliomyelitis, 9; encephalitis lethargica, 30; continued fever, 1; dysentery, 4; ophthalmia neonatorum, 85. There was no case of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 4 (0) from enteric fever, 94 (33) from measles, 9 (1) from scarlet fever, 18 (3) from whooping-cough, 64 (15) from diphtheria, 61 (10) from diarrhœa and enteritis under two years, and 120 (17) from influenza. The figures in parentheses are those for London itself. The deaths from enteric fever outside London occurred in Walthamstow, Bolton, Sheffield, Sunderland, one each. Of the 61 fatal cases of measles outside London 10 were reported from Bristol, 17 from Manchester, 2 from Salford, and 3 each from Derby, Liverpool, and Sheffield, while the figure from Glasgow for the same week was 39. The number of stillbirths registered during the week was 274 in the great towns, including 53 in London.

MEDICINE AND THE LAW.

The Un-open Road.

AFTER the Christmas blizzard, when the business world is reckoning up its commercial losses and when members of the public are recounting their personal inconveniences, the disorganisation of the health services of the country deserves a few words. If roads are blocked for several days by snow medical practitioners are immobilised, and hundreds of homes where the doctor is wanted are deprived of help and distracted by increased anxieties. To scold at the forces of nature is as impotent as to fold the hands in resignation to whatever comes from the heavens. Xerxes, when his bridge across the Hellespont was broken by a storm, ordered the sea to receive 300 lashes; but he also ordered the chiefs of his bridge-building department to be decapitated. The Ministry of Transport must not be surprised if it is asked what contribution it made towards the immediate removal of the obstructions on our main roads last week. Allowance, of course, must be made for the suddenness of our climatic changes, but the official meteorologists can tell the Ministry of the recurrence of a severe winter and their day-to-day prognostications have lately been unusually confident. Allowance, too, must be made for financial stringency, but the resources of the Road Fund should be as readily available for removing snow-drifts as for other forms of maintenance and improvement. If it is said that the Minister is not so much to blame as the hundreds of independent local authorities, has the Minister taken any step to stimulate and coördinate their activity? Nobody expects him to be responsible for the condition of every country lane, but the plight of a city like St. Albans inside the London traffic area, where he has special powers and duties, was deplorable. When the general strike threatened the freedom of the roads tanks and the full civil and military resources of the country were employed. The recent absence of central organisation and initiative, at a season when volunteers

could have been readily enlisted, was the more conspicuous. Is there any general scheme of snow-plough distribution? The railways for the most part cleared their cuttings with alacrity and success; can the Minister's specialists in road engineering devise no method for the rapid clearance of snow by mechanical devices? Or are our expensive public roads to be deemed merely a fine-weather luxury? Restraint upon State interference may be excellent in principle, but even the prompt issue of accurate information as to the condition of particular routes—a task facilitated by wireless broadcasting—seems to have been surrendered to the private bodies formed by motorists for their mutual protection. The Ministry of Transport has its critics; it has lost a chance to discomfit them.

Correspondence.

"Audi alteram partem."

THE PRESENT POSITION OF THE VOLUNTARY HOSPITAL.

To the Editor of THE LANCET.

SIR,—Having read with the greatest interest the address by Dr. Graham Little, M.P., in your issue of Dec. 17th, 1927, I think it would be indecent of me to refrain from commenting on this matter. His address and conclusions bristle with points of controversy and fallacy like "quills upon the fretful porcupine." The obvious error into which he has fallen is that of describing a condition existing in a small area of London, and from that, generalising for the whole of the country. It is just as easy for any other person to generalise in a similar manner and, with your permission and subject to your correction, I will do so without going so very far from London after all.

The hospital which I have the privilege to direct is not a voluntary hospital but belongs to what I like to call the involuntary class, which nevertheless has to turn out the work. The area from which patients are drawn is 70 square miles, somewhat greater than half the metropolitan area of London (118 square miles), and from the very outset of its career the North Middlesex Hospital (Edmonton, N. 18) has been in the unique position of having to deal with patients from this dormitory area in all and every circumstance and illness, excepting notifiable and infectious diseases. A teaching hospital affiliated to a university is, of course, a thing apart, and will always attract some of the best men in the profession, but I do not think that Dr. Little is justified in his sweeping conclusions as far as many large non-teaching involuntary hospitals are concerned, as there *are* many such in the country, doing the most excellent work, with every facility for research and scientific treatment.

Under the heading "Bureaucratic Ideals," Dr. Little has an opportunity for introducing political views. As I am not a politician I cannot meet him on equal ground, except to suggest that it might be equally feasible to discuss some hospitals under the heading "Autocratic Ideals." These high-sounding phrases are merely words and definite actions speak much louder. Sir Arthur Stanley is true when he talks of "the great increase of confidence on the part of the general public in the treatment which they receive when they enter the hospitals," but this applies to *all* good hospitals, no matter what be the nature of their origin. Sir Arthur Stanley has been to see our work at Edmonton, and if I mistake not his words, he was very much impressed, not just by "bricks and mortar," but by other amenities common to all medical workers with proper ideals of service.

The author of "Voluntary Hospitals in Great Britain (excepting London)" paid us a visit ten days ago, and on the occasion of his visit, Mr. R. H. P. Orde, Director of Hospital Services, St. John of Jerusalem and British Red Cross Society, saw quite a series of items of interest, apparatus for advanced technique, &c., in use here which cannot be seen in any voluntary hospital in Britain.

Without proceeding further, I should like to ask Dr. Little two questions: (1) Will he come here and see an example of what I believe to be a properly efficient involuntary hospital? (2) Will he answer the question which has puzzled me for so long, What is the difference between (say) a poor-law appendix and a voluntary appendix?

I am, Sir, yours faithfully,

SPENCER MORT, M.S., M.D., F.R.S. Edin.,
Medical Superintendent and Surgical Director,
North Middlesex Hospital.

Silver-street, Upper Edmonton, N. 18,
Dec. 28th, 1927.

ANÆSTHESIA FOR OPENING RETRO-PHARYNGEAL ABSCESS.

To the Editor of THE LANCET.

SIR,—May I be permitted to take exception to one passage in Mr. Hasler's otherwise admirable instructions on the "Treatment of Emergencies in Anæsthesia" in your issue of Dec. 31st, 1927? The statement that "in cases of retropharyngeal abscess . . . if a general anæsthetic is required it should be given either by the intratracheal method or through a laryngotomy tube," will not, I think, meet with general acquiescence. The condition referred to is most usually met with in children and the necessary operation requires neither a long nor a profound anæsthesia. In fact the degree of narcosis needed for safe performance of the operation is generally insufficient for passage of an intratracheal catheter. This is also undesirable because of the likelihood of rupture of the abscess during the necessary manipulation. By having the child kept on its side during the administration of the anæsthetic, or with the head extended over the end of the table, with a gag slightly opened resting in the upper side of the mouth and the head below the level of the chest, an open anæsthetic can be given to these patients to a degree which permits the operator to do all that he wishes when, relaxation being reached, the gag is widely opened. By proper management of the child's position risk of inhaling pus is excluded and there is no need to resort to laryngotomy. For young infants it is often possible and expedient to do without any anæsthetic at all. It seems to me that it would be a mistake to allow Mr. Hasler's recommendation to assume unchallenged the authoritative position which its appearance in your pages bestows upon it.

I am, Sir, yours faithfully,

St. Mary's Mansions, Paddington, W., J. BLOMFIELD.
Jan. 2nd, 1928.

RECURRENT COLDS.

To the Editor of THE LANCET.

SIR,—I have read with special interest the letter of Mr. Mark Clement in your issue of Dec. 31st, 1927, because my own experience bears out the views expressed. For 12 consecutive months when house surgeon and house physician at the Liverpool Royal Infirmary I slept in the open air. At the same time I discarded underclothing and began to take a daily cold shower. This régime began in the mild April of 1926 and continued throughout the winter, when in spite of fogs and bad general conditions I did not catch cold. This is notable in view of the fact that in previous years I had difficulty in avoiding colds and that medical officers of large institutions seem prone to colds and minor ailments being, on the whole, overworked and underexercised. The bed used was of an ordinary type, protected from blowing rain by a tarpaulin. In winter it was the custom to spray the nose before retiring with a preparation as follows: Eucalyptol gr. i., camphor gr. i., menthol gr. i., liquid paraffin ℥ i.

I am, Sir, yours faithfully,

C. ALLAN BIRCH.

Royal Infirmary, Liverpool, Jan. 3rd, 1928.

SACRO-ILIAC SUBLUXATION.

To the Editor of THE LANCET.

SIR,—I was an assistant to Goldthwait of Boston for two years and naturally am interested in your annotation in the issue of Dec. 17th, 1927, and in Dr. Mennell's letter in the issue of the 31st, in regard to sacro-iliac subluxation. In Goldthwait's clinic I saw many cases of sacro-iliac strain and injury and meet with these cases frequently at the present time. It is important to differentiate between cases of strain and subluxation of the sacro-iliac joint. Strains of the sacro-iliac joint are of frequent occurrence. Actual subluxation, with demonstrable displacement clinically and by X rays occurs, but is not common. I can recall six cases in Boston, where I was convinced that subluxation had taken place. An X ray of the whole pelvis is required. It should be taken stereoscopically, when asymmetry at the symphysis pubis is the most valuable positive sign.

Strapping and suitable supports are of value only after the subluxation has been corrected by manipulation under an anæsthetic. They are to be regarded as necessary makeshifts, until re-education of the muscles of the trunk and pelvis, to correct the faulty statics, has been completed; for it is the tone and correct use of the muscles which control and maintain the integrity of the spinal joints to a greater degree than the ligaments. Smith Petersen has reported recently the end-results of 30 cases of relaxation of the sacro-iliac joint, with relief of symptoms by operation. He started his investigations as a sceptic and submitted all his cases to a most searching physical, neurological, and radiological examination. I saw a number of these cases and felt convinced of the soundness of his claims in this regard. I have had two cases of true subluxation during the last year.

From being endemic in Boston, strain and subluxation of the sacro-iliac joint have now become epidemic all over America. The reason for this lies, in my view, in the fact that traumatic affections of the sacro-iliac joint are common and that American surgeons are gradually learning the lessons which Goldthwait has taken so much trouble to teach. I would submit, further, that most of the obscurity in regard to cases complaining of "low back pain" is explained by a general lack of knowledge as to how a systematic physical examination should be carried out. There is no easy road for learning it, and without close study, also, it is difficult to interpret the facts properly. Cases of backache and sciatica are capable of scientific analysis and classification at the present time, and they include the important and frequent class of case which is the subject of your interesting annotation. I hope it will stimulate interest in this country, for there is no doubt that these cases are very largely neglected, important as they are in regard to frequency, lack of accurate diagnosis, and in knowledge of the appropriate treatment of the different lesions.

I am, Sir, yours faithfully,

Edinburgh, Jan. 1st, 1928. W. A. COCHRANE.

THE PREVENTION OF DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—The letter from Dr. S. Rowland, M.O.H. for Northampton, in your issue of Dec. 24th, 1927, appears to suggest that he has some doubt as to the value of immunisation in diphtheria. It would be interesting to know: (1) whether Dr. Rowland has himself had any personal experience of this method; (2) exactly what hospitals he refers to in the last paragraph of his letter where he states that "From what one has heard first hand from those who have worked in hospitals where Schick's method was practised, I feel for the present we must return for Schick the same verdict you brought in for B.C.G.—viz., not proven."

Such statements should, I feel, not be made without giving specifically the names of the hospitals concerned and the workers responsible for such statements. Dr. Rowland quotes an article by Drs. Harries, Macfarlane, and Gilhespy, but does not mention that the writers are among those most convinced of the value of the Schick method and, in fact, that the last paragraph of the article which he quotes states that the best method of rendering a "carrier" innocuous is to ensure that he should live "amongst children who have also been rendered immune by the safe and certain means provided by toxin-antitoxin."

The rest of Dr. Rowland's letter does not appear to deal with the question at issue. In the report issued by Dr. J. Graham Forbes upon "The Prevention of Diphtheria" Dr. Forbes showed that while the (septennial) attack-rate from 1904–24 had risen from 11·2 to 19·1, the death-rate had also risen from 0·99 to 1·33, showing that the suggested explanation of the increased incidence given by Dr. Rowland is a fallacious one. As far as I know every medical officer who has had practical experience of the Schick method, both as regards the test and as regards immunisation, is convinced of its extreme value in the prevention of diphtheria.

The report of the Public Health Committee of the London County Council can only be considered by such medical officers as a highly unsatisfactory one. It has been demonstrated in Edinburgh that immunisation among children can only be carried out satisfactorily on a large scale through the school organisations, and it is a great pity that the Edinburgh system could not have been brought into force in London. The fact that diphtheria has waves of high and low incidence has nothing to do with the matter. The point at issue is that we have in the Schick method the means of preventing susceptible children from contracting diphtheria during their school life and parents should have the means at their disposal of availing themselves of the method. Whether immunisation would lessen to any great degree the number of cases of diphtheria would obviously depend on the number which were immunised each year.

I am, Sir, yours faithfully,

A. H. G. BURTON,

Jan. 2nd, 1928. Medical Officer of Health, Ilford.

AN OPERATION FOR THE ALLEVIATION OF DEAFNESS.

To the Editor of THE LANCET.

SIR,—The idea of relieving the deafness in cases of marked Eustachian obstruction, with its concomitant non-suppurative tympanic lesions, by providing a permanent opening for ventilation between the mastoid antrum and the adjacent portion of the meatus, occurred to others many years ago. The claims, however, of Malherbe and Garnault have neither been confirmed nor accepted by competent and reputable otologists, either here or abroad;, and I am only performing an obvious duty in pointing out that the extensive operative interference advocated by Mr. Nesfield is, by a general consensus of otological opinion, considered useless and therefore unjustifiable in the class of case under discussion.

Can Mr. Nesfield bring forward cases which were seen and tested by a trained otologist, both before and after treatment, in which he alleges substantial improvement to have taken place? If not, I suggest his endeavouring to find an experienced otologist who could be induced to consent to collaborate with him, in his future aural ventures, if he would overcome the scepticism of authority.

Although I have stated without misplaced modesty and timidity what I believe to be the position of authority, I admit that there is just a possibility—almost a forlorn hope—that authority may be in error here and Mr. Nesfield may be right and therefore a genuine benefactor to sufferers from obstinate obstructive catarrhal deafness.

I am, Sir, yours faithfully,

London, W., Jan. 3rd. WILLIAM HILL.

To the Editor of THE LANCET.

SIR,—In his book, "Otitis Media (Mastoid Disease)," which I have seen for the first time, Mr. Heath says

(p. 4): "Mastoid disease is one of the commonest ailments with which our army is troubled." I was the surgical specialist of the Lucknow Division as long ago as 1906, and so naturally saw a great deal of mastoid disease, as aural surgery, particularly mastoid disease, was not separated from general surgery. A civil surgeon in the old Indian Medical Service could not be a specialist; he had to deal with every branch of medicine and surgery, and be an expert in every department. As a matter of fact, specialism quite often impedes advance, as it limits scope and cramps the horizon. This may possibly be the reason that general surgeons have been responsible for outstanding advancements in the special branches—e.g., enlargement of the prostate, stone in the bladder, cataract, and so forth.

Acute mastoids are naturally a common emergency, and so I have had to operate on many hundreds. In 1901 I was taught Stacke's operation at St. Mary's Hospital. But before 1906 I, like many other surgeons, attempted to preserve the hearing in acute mastoid disease by draining the middle ear through the mastoid without destroying the eardrum and ossicles. I was in India in 1906, and did not know of Mr. Heath's article in your journal, but the important point is that *Mr. Heath's operation is for otitis media, otorrhœa, and perforation of the ear-drum.* He says: "... I exhibited 10 cases ... their perforated drums had healed." That his operation is for mastoiditis is clearly demonstrated by the advertisement of his book on the cover of THE LANCET. My attempt has been to alleviate deafness by operating on patients with normal ear-drums, and whose middle ears are not inflamed or purulent.

Wilde, Schwartze of Haale (1873), Stacke (1892), Ballance and Macewen were, I believe, the pioneers who taught us to gouge through the mastoid to hidden pus, and clear away all diseased bone. My aim has been to bore through the mastoid with as little injury as possible to the mucous membrane of the air cells, so as to produce a membrane-lined channel connecting the middle ear with the external auditory canal—i.e., *in effect to make a new Eustachian tube.* It must be clearly understood that I make this channel on ears healthy except for deafness. I know that to improve deafness in such cases Mr. Heath's treatment has not been to operate but to blister the ear-drum, because some of these (blistered) patients have since come to me, and I have made on them the channel I describe, and have alleviated their deafness.

Mr. Barford has been most kind, and I appreciate his remarks. Nearly all my cases have been frequently catheterised, and an attempt made to open their Eustachian tubes with bougies. Here again one has to recognise that the Eustachian tube opens into a small closed space (the middle ear), so that air is blown into a closed tube. It is, therefore, not surprising that mucus is not dislodged, and, if dislodged, is blown into the middle ear. On the other hand, when a channel has been made connecting the middle ear and the external auditory canal, air can most easily be blown right through the Eustachian tube and middle ear out of the external auditory meatus. For my part I prefer passing a stream of mild antiseptic fluid from the external auditory meatus through the middle ear and Eustachian tube into the pharynx.

The operation, if performed with phenolaine (a local anæsthetic), and very light chloroform anæsthesia is without risk. Why should we therefore hesitate to operate when the usual remedies of nasal douches, nasal operations, removal of tonsils and adenoids, catheterisation, &c., of the Eustachian tubes fail? I shall always be pleased to demonstrate cases.

I am, Sir, yours faithfully,

V. NESFIELD, F.R.C.S.,
Major, I.M.S. (ret.).

Sandhurst, Kent, Jan. 2nd.

AURAL SYSTEMIC INFECTION.

To the Editor of THE LANCET.

SIR,—Dr. R. D. Owen's article in your issue of Dec. 31st, 1927, prompts me to record that the treatment which I have found of the greatest value in such cases is the administration of *Scarlet Fever* Antistreptococcus serum (P., D. and Co.). I used this first in April, 1927, in a case of blood infection with hæmolytic streptococcus from an acute mastoiditis, and the effect can only be described as miraculous. Since that date I have used the serum in other cases, always with satisfactory result; it should be noted that the cases to which I refer were patients where there was no question of scarlet fever. I need not here go into details of these cases, as I hope shortly to publish a full account. Meantime I wish to emphasise the value of this treatment in the hope that others may find it helpful. Large doses may be given; in my first case so treated the serum was given intravenously in doses of one million units, repeated daily for ten days.

I am, Sir, yours faithfully,

H. ROSS SOUPER,
Aural Surgeon, Royal Aberdeen Hospital for Sick Children.

Dec. 31st, 1927.

To the Editor of THE LANCET.

SIR,—Dr. Owen has described a fairly typical case of systemic infection occurring in the course of mastoiditis. He would have been saved considerable anxiety as to the condition of the lateral sinus if he had carried out a small point of operative technique, which I have advocated elsewhere. In such cases, the lateral sinus should be freely exposed at the primary operation for half an inch or more, so that its subsequent state can be easily observed through the mastoid wound. If pulsation be observed during the periods of high temperature it is certain that thrombosis in the sinus is not present, and hence ligation of the jugular vein in the neck is unnecessary.

I am, Sir, yours faithfully,

HAROLD KISCH.

Wimpole-street, W., Jan. 2nd, 1928.

WELFARE OF THE BLIND.—In view of the continued development of work among the blind owing to the operation of the Blind Persons Act, 1920, and the new problems constantly arising in connexion with this service, the Minister of Health has reappointed the Advisory Committee on the Welfare of the Blind for a further period of office. The Committee has been constituted so as to afford representation to the local authorities concerned with the working of the Blind Persons Act, 1920, and to voluntary agencies for the blind, as well as to organised blind workers. The chairman is the Right Hon. G. H. Roberts, and among the members are Dr. J. J. Butterworth, Dr. R. A. Lyster, and Dr. H. A. Powell. Mr. F. M. Chapman, of the Ministry of Health, will act as secretary.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Wednesday, Jan. 11th, at 3 P.M., at the Royal Eye Hospital, St. George's-circus, Mr. Griffith will give the first of a series of clinical demonstrations. On Jan. 26th, at 1.30 P.M., at St. Bartholomew's Hospital, Sir Thomas Horder will give a medical demonstration, and on Jan. 23rd, at 2 P.M., at the Queen Mary's Hospital, Stratford, Mr. A. E. Mortimer Woolf will give a surgical demonstration. On Monday, Jan. 16th, at 5 P.M., Sir James Purves-Stewart will lecture on Acute Drunkenness. This lecture and demonstrations are free to members of the medical profession. From Jan. 9th, for a fortnight, from 10.30 A.M. to 5.30 P.M., at the North-East London Post-Graduate College (Prince of Wales's General Hospital, Tottenham) a special course will be held in medicine, surgery, and special department work, and will consist of demonstrations, ward-rounds, lectures, and operations. Between the same dates a course in diseases of children, organised by Dr. Bernard Myers, will be held at the Children's Clinic, the National Heart Hospital, the Royal Waterloo Hospital, the Hospital for Consumption, Brompton, and the Royal National Orthopædic Hospital, and will occupy most mornings and afternoons. From Jan. 16th–27th, at the National Hospital for Diseases of the Heart, an all-day course will be given (entries limited to 20), and from Jan. 17th to Feb. 11th, on Tuesdays and Saturdays, at 11 A.M., at the Bethlem Royal Hospital there will be a course of lecture-demonstrations on psychological medicine. Information, syllabuses, tickets, and copies of the *Post-Graduate Medical Journal* may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

Obituary.

SIR PERCY BASSETT-SMITH, K.C.B., C.M.G., F.R.C.P. LOND., F.R.C.S. ENG.

WE regret to chronicle the death of the distinguished naval officer and pathologist, Rear-Admiral Sir Percy Bassett-Smith, which occurred on Thursday, Dec. 29th, in his sixty-seventh year.

Percy Bassett-Smith was the son of Mr. William Bassett-Smith, of St. Albans, and received his general education at St. John's College, Hurstpierpoint. He entered the Middlesex Hospital as a young medical student, qualified as L.S.A., served the hospital as house physician to Sir Richard Douglas Powell, and entered the Naval Medical Service in 1883 at the age of 22, having now obtained the English double qualification; those who knew him personally will reflect that he must have looked a small lad for the responsibilities with which his commission endowed him. His opportunities of active service began before those of his actual contemporaries in age, for he served in the Egyptian Expedition despatched to re-establish the authority of the Khedive in 1882, and, his ship being engaged in military and naval operations during the next two years, he obtained the Egyptian medal and the Khedive Star. His successful start was followed by appointments in which he showed striking qualities of scientific as well as official nature; he obtained the Gilbert Blane gold medal for the best journal kept by an officer in medical charge of a warship, and in 1899 he was specially promoted fleet-surgeon. In the following year he was appointed lecturer on tropical medicine and hygiene at Haslar, where much of the research work was done that later formed the subject of valuable writing.

SIR PERCY BASSETT-SMITH.

Photograph by Elliott & Fry.

In 1906, having taken the tropical diploma at Cambridge, he won the Cragg's prize awarded for original research work by the London School of Tropical Medicine. In 1911 he was made C.B., and in 1912 was appointed professor of pathology and lecturer on tropical medicine at the Royal Naval College, Greenwich. This post he held for nine years, when he retired with the rank of surgeon rear-admiral and was created K.C.B., while his professional position had been recognised during his tenure of the post by election in 1916 both as F.R.C.P. Lond. and F.R.C.S. Eng. In 1918 he received the C.M.G.

The cessation of official connexion with the Admiralty left him free to practise as a consultant physician. He was immediately appointed to the staff of the City of London Hospital for the Diseases of the Chest and Lungs, and after three years as assistant physician he received charge of wards, so that his energy and enthusiasm received a full outlet. He had joined the staff at an age when most men would have considered that they had earned a rest, but he threw himself into the new duties with zeal and devotion, as was well displayed in his action, after appointment as in-patient physician, in voluntarily continuing his out-patient work. For this purpose he went down to the hospital regularly every Saturday afternoon, and when the artificial sunlight department was opened at the institution he added the supervision of this to his other responsibilities. His long experience at Greenwich made him keenly interested in all developments of clinical pathology, and any new laboratory test, which had a reasonable claim upon attention, was sure of open-minded reception from him. One of his colleagues writes: "Sir Percy was a man of quick and ready sympathies, and was always ready to help. A generous kindness characterised everything he did, and the writer never knew him to pass an uncharitable judgment." That summary of Bassett-Smith as a hospital officer may be applied to his general activity in public affairs. On the Council of Epsom College he was a regular attendant, an advocate of all developments of the institution as a public school, and a kindly scrutineer of the claims for scholarships and pensions.

He served for two years as President of the Royal Society of Tropical Medicine and Hygiene, and was tropical specialist to the Appeal Board of the Ministry of Health. No text-book came from him, and his writings were based entirely upon his work in the Navy. In this way he acted for a time as assistant editor of the *Bulletin of Tropical Disease*, issued by the Bureau of Hygiene and Tropical Diseases, and made many useful contributions to medical literature through this and various journals and medical systems. He wrote on the poisons of snakes and fishes in the "Encyclopædia Medica"; on undulant fever in Byam and Archibald's "Practical Medicine in the Tropics," in THE LANCET, and in the *Journal of Tropical Disease and Hygiene*; and on parasitic splenomegaly in the *British Medical Journal*. The three last papers from his pen were published in our columns—The Carriers of the Meningococcus: A Year's Record, in 1918; The Preservation of Lemon Juice in 1920; and Prevention of Scurvy in the Navy, 1921. All three papers exhibit similar qualities of care, accuracy, and inclusiveness; the last, which was read before the War Section of the Royal Society of Medicine, was a practical contribution to our knowledge of the prophylaxis of scurvy. Bassett-Smith, in fact, placed both the Navy and Army in his debt by his work in preparing the efficient and portable antiscorbutic remedy which he exhibited in lozenge form to the Society.

One who as a colleague was familiar with Bassett-Smith's ideals and conduct of work writes as follows:—

Sir Percy Bassett-Smith will be missed by many, as there were many who were glad to call him friend. There was a good deal of the sailor about him, for, although he spent most of his life in hospitals and laboratories ashore, he carried with him a certain cheeriness and breeziness which endeared him to his colleagues. An affectionate regard led to his being often called the "little gentleman," and the title was well bestowed. He was a man who never stooped to anything mean or underhand, nor did he speak evil of his neighbours. He was a friendly soul, full of vigour, persistence, and energy, and it was these qualities of mind and body, together with a ripe experience and a sound and sane outlook on life, which led to his success in various directions. To him idleness was abhorrent and when, much to his sorrow, he had to give up his life's work in the Navy, where, by the way, he gained for himself a unique position, he plunged into a maze of activities, examining and treating patients, examining students in tropical medicine, continuing his duties as sectional editor for the Bureau of Hygiene and Tropical Diseases, taking a prominent share in the work of the Royal Society of Tropical Medicine and Hygiene, of which for two years he was President, much to his joy and satisfaction, lecturing, attending meetings and demonstrations and keeping himself generally abreast of the times. He was not a good public speaker; he had no great

facility with the pen, but he had a thorough knowledge of the subjects in which he was specially interested, notably undulant fever and the deficiency diseases, a good general knowledge of laboratory and clinical work, and he never spared himself. Above all he had, like the service to which he was proud to belong, a great and abiding sense of duty, and so he earned the liking and respect of his fellows and rose to high office amongst them. He died in harness, as no doubt he would himself have chosen, for he would have dreaded any approach to the stage of the "slippered pantaloon"; but his loss will be severely felt in those circles wherein he moved and where, as the "little gentleman," he was ever welcome.

Sir Percy Bassett-Smith married Constance, daughter of the Rev. F. Hastings, who died two years ago, by whom he leaves two daughters. His death took place at St. John's Hospital, Lewisham, and was the result of septicæmia incurred at a post-mortem examination.

MICHAEL JOSEPH MAHONY, D.S.O., M.D. N.U.I.

Dr. Mahony died on Dec. 23rd at his home at Stoneycroft, Liverpool, where he had practised for some 35 years and had gained the affection of a large circle. Born at Waterford, the son of Mr. Richard Mahony, he was educated at St. Vincent's College, Castleknock, and graduated in medicine in the Royal University of Ireland in 1890. Two years later he started practice in Liverpool, and in the South African war he held a combatant commission in the Liverpool Volunteers, being awarded the Queen's medal and three clasps. After the war he remained for some time in South Africa, but eventually returned to Stoneycroft to his ever-increasing practice, and to his public work in connexion with numerous institutions in the neighbourhood. These included the Hospice for the Dying in Liverpool, of which he was one of the founders. On the outbreak of the late war Dr. Mahony went to France as major in the Royal Army Medical Corps (Territorials) attached to the 9th King's Liverpool Regiment. At the end of 1915 he was invalided home but later rejoined for service on the Somme with the 5th battalion. He was one of the first three officers of the 55th Division to be recommended for the D.S.O., which he received in 1917, and in addition he was twice mentioned in despatches, and was awarded the Médaille de reconnaissance française (en argent).

Dr. Mahony's death followed closely on that of his father, and they were buried together at West Derby on Dec. 27th with military honours.

ARTHUR GOULSTON, M.D. CAMB.

Dr. Arthur Goulston, who died at Charlcombe Rectory, Bath, on Dec. 22nd, received his medical education at Cambridge and St. Thomas's Hospital, and after qualifying as M.R.C.S. Eng. in 1888, settled in practice at Exeter. In 1911, 23 years after qualification, he graduated as M.B. Camb., and in the following year proceeded to the M.D. degree with a thesis on the beneficial effects of cane sugar on the myocardium in certain forms of heart disease. In this subject he had interested himself for some eight years, and he published a number of articles expounding the favourable views he formed. In 1914 these were further set out in a book entitled "Cane Sugar and Heart Disease," in which he explained that he had first tried the treatment because sugar was used in the German army and amongst Alpine climbers to combat undue cardiac strain. His clinical investigations brought him the Hunterian Society's medal in 1912. He remained in general practice at Exeter until some six years ago, when he moved to London. Dr. Goulston held the Volunteer Decoration. Last year he retired and went to live at Bath.

WE are asked to state that the Central Information Bureau, which has its offices in the Kaiserin Friedrich-Haus, Berlin, N.W. 6, Luisenplatz 2/4, gives information free of charge in all matters relating to medical questions in Germany.

Medical News.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on Dec. 14th, 1927, it was resolved to institute a chair of chemistry as applied to hygiene, and a chair of public health, both tenable at the London School of Hygiene and Tropical Medicine.

University College.—A course for the Diploma of Public Health opens early this month. Details may be had from the Secretary.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Six Hunterian lectures on Factors Concerned in the Growth of the Human Body will be delivered in the theatre of the College, Lincoln's Inn-fields, by Sir Arthur Keith, F.R.S., Conservator of the Museum, at 5 P.M., on Mondays, Wednesdays, and Fridays, Jan. 16th, 18th, 20th, 23rd, 25th, and 27th.

CONFERENCE ON RHEUMATIC DISEASES.—A conference on rheumatic diseases is to be held at Bath on May 10th and 11th. Sir George Newman will act as President of the conference, of which the three sessions will be devoted respectively to social aspects, causation, and treatment. The local hon. medical secretary is Dr. Vincent Coates, 10, Circus, Bath.

ROYAL INSTITUTE OF PUBLIC HEALTH.—A course of lectures on Problems of Forensic Medicine will be given at the Institute, 37, Russell-square, London, W.C. at 4.30 P.M., on Wednesdays, from Jan. 18th to March 14th. The lecturers will be: Mr. Roland Burrows, Dr. Godfrey Carter, Dr. Nathan Raw, Dr. Norwood East, Dr. W. M. Feldman, Dr. Whitley MacFall, Sir Robert Armstrong-Jones, Dr. Roche Lynch, and Dr. Robert Donaldson. Particulars will be found each week in our Medical Diary. Students and members of the medical profession are invited to attend.

ORTHOPÆDICS AT BIRMINGHAM.—Two years ago the Birmingham Cripples' Union and the Royal Orthopædic Hospital were amalgamated under the cumbrous title of "The Birmingham Cripples' Union and Royal Orthopædic and Spinal Hospital (Amalgamated)." The designation has now been altered, with the King's permission, to "The Royal Cripples' Hospital, Birmingham."

PRESERVATIVES IN FOOD.—The Public Health (Preservatives, &c., in Food) Regulations came into force on Jan. 1st so far as they relate to butter, cream, and articles of food containing preserved bacon, ham, egg yolk, or cream. As it may not be practicable to get rid of all stocks of preserved butter at once the Minister of Health has suggested to local authorities that they should refrain from instituting legal proceedings during the first few weeks of the year, if they are satisfied that reasonable efforts have been made to clear old stocks.

HUNTERIAN SOCIETY.—The Hunterian lecture will be given at 9 P.M. on Monday, Jan. 16th, by Dr. Howard Kelly, of Baltimore, U.S.A., who has chosen to speak on Emergent Gynæcology. The annual dinner will be held on Thursday, Feb. 9th, at the Hotel Victoria, and the Hunterian oration will be given on Monday, Feb. 27th, at the Mansion House by Dr. Anthony Feiling. His subject will be Sciatica—Its Varieties and Treatment. On Monday, March 19th, at 7.30 P.M., there will be a dinner meeting at Simpson's Restaurant, Cheapside, when Dr. Robert Hutchison and Sir Farquhar Buzzard will open a discusson on Hiccup. The last fixture of the season will be the annual general meeting on April 23rd.

ROYAL SOCIETY OF MEDICINE.—The new session promises combined discussions on a number of important topics, among them the influence of naso-aural sepsis on the lungs and gastro-intestinal tract (Jan. 11th), in which the three sections of Laryngology, Medicine, and Odontology will take part, and a special discussion on cutaneous mycosis in the tropics (Jan. 25th), arranged jointly by the sections of Tropical Diseases, Dermatology, and Comparative Medicine, to which members of the War Section are specially invited. At the Section of Psychiatry on Jan. 10th Dr. William Brown will read a paper on theories of suggestion. At the Section of Electrotherapeutics on Jan. 20th Prof. Sidney Russ and Dr. T. F. Cotton will introduce a discussion on diathermy in relation to circulatory disturbances, and on Jan. 27th Dr. J. E. McCartney will make some observations on diphtheria carriers to the Section of Epidemiology. The next social evening will, as already announced, be held on Monday, Jan. 16th, when Dr. Jane Walker will give an illustrated address entitled Saints, Medicine, and Surgery. The Secretary of the Society will be glad to receive the names of Dominion and foreign physicians who are visiting this country, in order that invitations to attend the social evening may be sent to them.

SOCIETY FOR THE STUDY OF INEBRIETY.—At 4 P.M. on Tuesday, Jan. 10th, at the rooms of the Medical Society of London, 11, Chandos-street, W., Prof. Hugh MacLean will open a discussion on Alcohol and Alcoholism in Relation to Problems of Nutrition and Health. Members and Associates may introduce visitors.

LECTURES ON INFANT CARE.—A course of advanced lectures especially intended for creche nurses and probationers have been arranged by the National Association for the Prevention of Infant Mortality and the National Society of Day Nurseries, and will be held on Thursdays, from 7.30 to 8.30 P.M., from Jan. 12th to March 15th, at Carnegie House, 117, Piccadilly, London, W.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The first meeting of this year will be held at 5 P.M. on Jan. 20th, when Dr. Walter Elliot, M.P., and Prof. R. H. A. Plimmer will speak on Recent Advances in the Knowledge of Food. On Feb. 17th, at the same hour, Dr. G. F. Buchan and Dr. A. F. Cameron will open a discussion on the Control of Small-pox, and on April 20th Sir Robert Philip, Dr. W. M. Willoughby, Prof. E. L. Collis, and Prof. Major Greenwood will address a general meeting at Bath on the Causes of the Decline in Tuberculosis Mortality. The first two meetings will be held at 1, Upper Montague-street, Russell-square, London, W.C.

MEDICAL SOCIETY OF LONDON.—The spring session opens on Monday, Jan. 9th, with a pathological evening; a fortnight later the treatment of pernicious anæmia will be introduced by Prof. F. R. Fraser and discussed by Sir William Willcox and Dr. Herbert French. Other subjects on the agenda for Monday evening meetings are the use and abuse of ultra-violet therapy, the scope of surgery in the treatment of chronic rheumatoid and osteo-arthritis, the carrier problem, and recent advances in the treatment of cancer of the cervix uteri. On three evenings in February and March Dr. F. J. Poynton will deliver the Lettsomian lectures on rheumatic heart disease in childhood. The annual dinner will be held at the Trocadero Restaurant on Thursday, March 8th, while the session will finish up with the general meeting on Monday, May 14th, when Sir Archibald Garrod will deliver an oration entitled Lessons on Rare Maladies.

ROYAL SOCIETY.—Applications are invited for a Foulerton Research Professorship, tenable for five years and renewable for further periods. The holder will be expected to undertake original research in medicine or the contributory sciences, on lines approved by the committee of the Foulerton Research Fund. In awarding professorships the chief consideration will be the candidate's ability rather than the subject of his research. The professor will devote his whole time to investigation, except that he may give a limited course of instruction to advanced students; in special cases, however, the holder of a paid academic or other scientific appointment may be elected, provided that the duties of this appointment are only subsidiary to those of his Foulerton professorship. Members of all nationalities and both sexes are eligible, and applications must reach the Society not later than Sept. 30th. Further particulars may be found in our advertisement columns.

JAMES MACKENZIE INSTITUTE FOR CLINICAL RESEARCH.—At a meeting held on Dec. 6th, 1927, Sir George Lenthal Cheatle read a paper entitled Some Recent Views on Carcinoma as Applied to the Colon. He described two types of epithelial hyperplasia which he had found in his research on the breast. The first type, associated with increase in peri-canalicular and peri-acinous connective tissue, was seen in the breast of the newly-born infant and at puberty and might therefore be regarded as physiological. He protested against the use of the term chronic mastitis in this connexion, since the condition was not inflammatory. He did not agree that this hyperplasia was secondary to increased vascularity, but considered that the increased vascularity present was the result of greater functional activity. In the second type of hyperplastic change the epithelial cells tended to heap themselves upon one another, and this process led to the formation of cysts and papillomata. In the colon he had been unable to discover anything comparable to the first type, but the second type of overgrowth was common. In the breast and colon such papillomata might be innumerable and they were commonly associated with carcinoma. The epithelial activity was, in his opinion, always the essential change. A cell, having taken on the malignant character, invaded surrounding tissue and at this stage the invasion was the only proof of its malignancy. The lecturer described the following types of spread in the colon: (*a*) limited spread in the submucous lymphatics; (*b*) direct spread of epithelial cells in the circumrectal fat; (*c*) embolic spread (rarely); (*d*) diffuse explosive local spread in all tissues; and (*e*) invasion of radicals of proctal vein. The last of these, he said, explained the frequent invasion of the liver in carcinoma of the bowel.

SOCIETY OF APOTHECARIES OF LONDON.—A Livery Dinner of this Society was given on Tuesday, Jan. 3rd, to the Lord Mayor of London and Sheriffs, when occasion was made for the presentation to Sir F. Gowland Hopkins of the Society's medal for distinguished therapeutic research. The Master, Dr. R. Whiteside Statham, presided, supported by Lieut.-Colonel C. T. Samman, R.A.M.C., and Dr. H. J. Ilott, the Wardens.

After the loyal toasts, the Master proposed the health of the Lord Mayor, Sir Charles Batho, associating the Sheriffs with his words. He briefly narrated some points in the history of the Society, and explained how it came to lose its place among "the great twelve," although ancient descent could be claimed for it from the herb merchants of biblical days, while the name apothecary was derived from Galen's word for a herb repository. The incorporation of the Society actually dated, he said, from the reign of James I. whose apothecary, Gideon Delaune, was the principal medium for securing the charter and finding the money for the original hall. He reminded the audience that the bust on the bracket at the upper end of the hall represented this famous man, who is reported to have lived till the age of 97, and to have married in middle life and been the father of 37 children by one spouse. The Master closed his speech by referring to the activity of the Society in instituting a diploma in midwifery, the arrangements for which were now complete.

The Lord Mayor and Mr. Sheriff Davenport having replied, the Master then presented the gold medal of the Society for his work on nutrition to Sir Gowland Hopkins. He described him as our greatest living biochemist, filling the first university chair in that subject which had recently been instituted at Cambridge, and referred to the spread of exact knowledge in regard to diet that had followed upon the discovery of the vitamins from A to E. He hoped that the dinner that evening had been properly selected in respect of vitamins.

Sir Gowland Hopkins, in returning thanks for the medal, disclaimed having done any work in respect of vitamin E, but said that from experiments on rats the presence of this vitamin appeared to quadruple procreative powers. Speaking generally of the subject of nutrition, he held that no section of the human race had ever been properly nourished, whether we were considering aborigines who ate berries or, at the other end of the scale, the feasts of city magnates. The vitamins were certainly well represented at the present dinner in quantity, if not in distribution. He held that the disabilities of man, due to age-long malnutrition, were undoubted, and that the whole subject of nutrition formed urgent material for research.

Colonel Samman, in proposing the health of the guests, made special mention of Sir Frederic Hallett, whom he congratulated on his recent honour, calling his work in the cause of medical education admirable and far reaching. He associated with the toast Dr. Graham Little, Member of Parliament for the University of London, and Mr. Briscoe, Master of the Worshipful Company of Armourers and Brasiers.

Dr. Little, in reply, told of the progress of the University of London, and suggested that the City Companies should turn their attention to their own university rather than to the provincial institutions, for each of the Companies might very well endow the University with a chair or scholarship associated with their own titles. He suggested to the Master of the Cutlers Company, Dr. Atwood Thorne, and to the Master of the Butchers Company, Mr. Killby, who were among the guests, that a chair in operative surgery would be appropriate.

The speeches were interspersed with some charming singing by the Chauntry Gleemen.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Jan. 10th.—5 P.M., THERAPEUTICS. 8.30 P.M., PSYCHIATRY. Paper: Dr. William Brown: Theories of Suggestion.

WEDNESDAY.—8.15 P.M., LARYNGOLOGY, MEDICINE, ODONTOLOGY. Special Discussion on the Influence of Naso-oral Sepsis on the Lungs and Gastro-intestinal Tract. Openers: Mr. E. D. D. Davis and Mr. C. A. S. Ridout (for the Section of Laryngology), Dr. R. A. Young and Dr. T. Izod Bennett (for the Section of

Medicine), Mr. J. G. Turner and Mr. A. Bulleid (for the Section of Odontology).

THURSDAY.—8 P.M., NEUROLOGY. Clinical Meeting at the National Hospital, Queen-square, W.C.

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 5 P.M.) Cases: Dr. F. Parkes Weber: (1) Non-operated Mammary Carcinoma of Fifteen Years' Duration in a Woman with Strongly Positive Wassermann Reaction. Dr. Bernard Myers: (2) Specimens from a Case of Erythro-leukæmia. Dr. Philip Figdor: (3) A Case of Congenital Heart Disease. Other cases will be shown. 8.30 P.M., OPHTHALMOLOGY. (Cases at 8 P.M.) Papers, &c.: Mr. W. Stewart Duke-Elder: Factors Controlling Intra-ocular Pressure. Mr. Montague L. Hine: Report on a Case of Neurofibromatosis of the Eyelid and of an Artificial Eye which Burst in the Socket. Mr. E. Wolff: A Bend in the Sixth Cranial Nerve and its Clinical Significance (Anatomical Specimen).

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Jan. 9th.—8.30 P.M., Pathological Evening.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

MONDAY, Jan. 9th, to SATURDAY, Jan. 14th.—ROYAL EYE HOSPITAL, St. George's Circus, S.E. Special Clinical Demonstration in Ophthalmology. Tues., at 3 P.M., by Mr. Griffith. Free to members of the medical profession.—PRINCE OF WALES'S GENERAL HOSPITAL, Tottenham, N. Post-graduate course in medicine, surgery, and the special departments. Demonstrations, lectures, ward rounds, and operations.—CHILDREN'S CLINIC, and other hospitals. Post-graduate course in diseases of children, mornings and some afternoons.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, W.

MONDAY, Jan. 9th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Dr. Trevor Davies: Gynæcological Department. 4.30 P.M., Dr. Carmichael Low: Dysentery (lecture).

TUESDAY.—2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. MacDonald: Genito-urinary Department. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Special Medical Treatment Clinic. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department.

SATURDAY.—10 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Owen: Medical Diseases of Children.

Medical and Surgical Out-patients, Operations, Special Departments, daily, 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 1 P.M.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

THURSDAY, Jan. 12th.—5 P.M., Dr. J. M. H. MacLeod: Ringworm Infections.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

WEDNESDAY, Jan. 11th.—4 P.M., Consultations and Demonstrations of Interesting Cases.

FRIDAY.—4 P.M., Mr. A. Ryland: Demonstrations of Museum Specimens.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 10th.—3.15 P.M., Dr. W. H. McKinstry: Pathological Specimens. Dr. P. O. Ellison: Clinical Pathology.

ST. MARY'S HOSPITAL, Whitworth-street West, Manchester.

FRIDAY, Jan. 13th.—4.30 P.M., Dr. Fletcher Shaw: Antepartum Hæmorrhage.

Appointments.

COCHRANE, H. L., M.B., B.Ch. Belf., has been appointed House Surgeon, Royal Infirmary, Oldham.

NOON, C., F.R.C.S. Eng., Hon. Surgeon to the Patrick Stead Hospital, Halesworth, Suffolk.

YULE, J., M.B., Ch.B. Glasg., D.P.H., Assistant Port Medical Officer, Hull and Goole Port Sanitary Authority.

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital for Genito-Urinary Diseases, 49–57, Vauxhall Bridge-road, S.W.—Res. Sen. H.S. At rate of £200.

Birmingham City.—Sen. Asst. M.O.H. £1100.

Central London Ophthalmic Hospital, Judd-street, W.C.—Two Out-patient Officers. Each £150. Also Jun. H.S. At rate of £50.

City of London Hospital for Diseases of the Heart, Victoria Park, E.—P. to Out-patients.

Connaught Hospital for Walthamstow, Wanstead, and Leyton, Orford-road, E.—Hon. P.

Croydon County Borough.—Asst. M.O.H., &c. £600.

Derby, Derbyshire Royal Infirmary.—Hon. Gynæcologist.

Exeter, Royal Devon and Exeter Hospital.—Sen. H.S. £200.

Freemasons' Hospital and Nursing Home, 237, Fulham-road, S.W.—Res. M.O. At rate of £250.

Glasgow, Lightburn Joint Hospital, Shettleston, near Glasgow.—Res. Med. Supt. £300.

Glasgow Royal Cancer Hospital.—Cancer Research Worker. £800.

Hospital for Consumption and Diseases of Chest, Brompton, S.W.—H.P. £50 for six months.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—Hon. Asst. P.

Ipswich, East Suffolk and Ipswich Hospital.—Cas. O. £150.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Lincoln, The Lawn.—Med. Supt. £700.

Lowestoft, Suffolk, S. Luke's Hospital.—Jun. Asst. M.O. £500.

Manchester, Ancoats Hospital.—H.S. £100. Also Res. M.O. £150.

Manchester Royal Eye Hospital.—Two Jun. H.S.'s. Each £120.

Manchester Royal Infirmary.—Asst. M.O. £35.

Manchester, St. Mary's Hospitals.—Three H.S.'s. Each at rate of £50.

Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—Two H.S.'s. Each at rate of £200.

Middlesex Hospital Medical School, W.—Medical Registrarship. Also Obstetric and Gynæcological Registrar. Each £300.

Midlothian, West Lothian and Peebles Counties.—M.O.H. £900.

Norwich City.—Clinical Tuberculosis Officer, &c. £750.

Nottingham Children's Hospital.—Res. H.S. At rate of £150.

Oldham County Borough.—Res. Asst. M.O.H. £450.

Portsmouth City Mental Hospital.—Second Asst. M.O. £525.

Royal Air Force, Medical Branch.—Med. Offs.

Royal Army Medical Corps.—Limited number of Commissions.

Royal London Ophthalmic Hospital, City-road, E.C.—Asst. Surg.

Royal Naval Dental Service.—Five Dental Officers.

Royal Society, Burlington House, W.—Second Foulerton Research Professor. £1400.

St. John's Hospital for Dis. of Skin, 49, Leicester-square, W.C.—Pathologist. £150.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. At rate of £75.

St. Pancras Dispensary, 39, Oakley-square, W.C.—Res. M.O. £185.

Shanghai Municipal Council, Public Health Dept.—Asst. Pathologist. 600 Taels per mensem.

South London Hospital for Women, Clapham Common, S.W.—Clin. Assts.

Swindon Borough.—Asst. M.O.H. £600.

Sydney, Australia, Royal Prince Alfred Hospital.—Pathologist. £700.

Taunton and Somerset Hospital.—Sen. and Jun. House M.O.'s. At rate of £150 and £100 respectively.

Tonbridge Union Institution, Pembury, near Tunbridge Wells.—Res. Asst. M.O. £275.

Ventnor, Isle of Wight, Royal National Hospital for Consumption and Diseases of Chest.—Jun. Res. M.O. At rate of £300.

Victoria Hospital for Children, Tite-street, Chelsea, S.W.—H.P. and H.S. Each at rate of £100. Also two Out-patient Anæsthetists. 10*s.* 6*d.* per attendance.

Watford Peace Memorial Hospital.—Res. M.O. At rate of £150.

West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Sen. H.P. At rate of £150.

Woolwich and District War Memorial Hospital, Shooters Hill, S.E.—H.S. and H.P. Each £125.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Bracknell (Berks), Dollar (Clackmannanshire), and Holyhead (Anglesey).

The Secretary of State for the Home Department gives notice of a vacancy for a Medical Referee under the Workmen's Compensation Act for the districts of the Blandford, Bridport, Dorchester, Ringwood, Lymington, Poole and Bournemouth, Wareham, Weymouth, and Wimborne Minster County Courts. Applications from practitioners living in or near Dorchester or Weymouth should reach the Private Secretary, Home Office, Whitehall, London, S.W. 1, not later than Jan. 20th.

Births, Marriages, and Deaths.

BIRTHS.

COLLYNS.—On Dec. 23rd, 1927, the wife of Dr. P. C. Collyns, Dulverton, Somerset, of a son.

JONES.—On Dec. 21st, 1927, at Old Court, Ealing, W., the wife of Dr. W. Hewitt-Jones, of a son.

DEATHS.

ALLDEN.—On Dec. 26th, 1927, at Northgate House, Beccles, John Horatio Allden, M.R.C.S., L.R.C.P., aged 75.

BASSETT-SMITH.—On Dec. 29th, 1927, Surgeon Rear-Admiral Sir Percy Bassett-Smith, K.C.B., C.M.G., of 3, Aberdeen-terrace, Blackheath, S.E.

DENNY.—On Dec. 20th, 1927, at Ashfield-place, Debenham, Dr. Arthur William Denny, aged 58.

HARRIS.—On Dec. 25th, 1927, in London, Spencer Clabon Harris, L.R.F.P.S., L.M., L.S.A., late M.O.H. Ely, aged 73.

MILLER.—On Dec. 31st, 1927, suddenly, at Craiglinnhe, Fort-william, Lieut.-Colonel Alexander Cameron Miller, M.D., F.R.S.E.

TULK.—On Dec. 30th, 1927, at Poole, Dorset, Marmaduke James Tulk, M.D., M.R.C.S., aged 74.

WARREN.—On Dec. 26th, 1927, at Weston-super-Mare, Charles Edward Henderson Warren, M.B., M.R.C.S., aged 73.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE DISCOVERY OF THE ANÆSTHETIC POWERS OF NITROUS OXIDE.

By GEORGE PARKER, M.D. CAMB.,
CONSULTING PHYSICIAN TO THE BRISTOL GENERAL HOSPITAL.

THE first use of anæsthetics in surgery marks such an important era in human history that even the early steps in the story of their discovery are not without interest. Nitrous oxide was the first gaseous anæsthetic in modern times to have its properties tested and demonstrated, but since some curious doubts have been expressed as to the exact place and date of these investigations, and even as to the author of them, it may be worth while to review the existing evidence.

The Evidence Reviewed.

Dr. Priestley had isolated and inhaled oxygen in 1774, probably when staying at Bowood Park, Wilts, and either in 1772 or 1775 he discovered nitrous oxide. Our knowledge of gases was greatly extended about this time by Cavendish, Lavoisier, Black, and others; and the idea that some of these new gases might have great therapeutic properties when inhaled, appealed to many minds at the time. Indeed, a strong movement sprang up to test them, especially to obtain, if possible, a cure for consumption. The history of the effort falls into two stages, the first from, say, 1790 to 1798, and the second 1799 to 1810 or later. Dr. Beddoes, a brilliant Oxford lecturer on chemistry, was an early adherent, and in 1793 he got in touch with many able men all over the country who were investigating the effects of inhaling oxygen, hydrogen, carbonic acid, and "hydrocarbonate gas." He published and annotated the reports they sent in of their results in a volume of 500 pages entitled "Considerations on the Medicinal Use and Production of Factitious Airs, by Thomas Beddoes, M.D., and James Watt, Engineer, 1794." This quickly sold out, and editions in 1795 and 1796 followed. Watt gave to the association not only a valuable paper with fine drawings on the manufacture and storage of gases (down to a gasholder for conveyance in a postchaise), but also the help of the great firm of Boulton and Watt to devise and make reliable apparatus. The importance of this at that time is shown by Watt's own famous difficulties to find a man able to make a perfect steam cylinder.

It should be noted in this early period that the researches were confined to the gases above mentioned, and no paper appeared in the "Considerations" on nitrous oxide except one by S. Latham Mitchill, an American, who taught that it was so poisonous that a single inhalation of the pure gas would destroy life at once, and that it was actually the virus of the fevers and plague—a good reason for leaving all work on it till a slack time.

It has also been suggested that ether was among the gases investigated before nitrous oxide. The only ground for this is that in two of the many reports of treatment by inhalation of oxygen, &c., Pearson and Thornton said that they found 2 drachms of ether inhaled from a saucer or teapot helpful in phthisis, asthma, or catarrh, 1795, perhaps as we use Friar's balsam. The production of ether narcosis only began after Faraday, many years later on, announced that ether when deeply inhaled produced results similar to those which had been established for nitrous oxide already.

Beddoes's Experiments on Inhalation Treatment.

Beddoes was not content with registering the results of this collective investigation by others, and began experiments himself for the campaign against consumption. He first intended to commence in London, but finally settled in Clifton, 1793, where numbers of consumptives flocked to the Hotwells. With the help of friends he formed a laboratory in Hope-square and made detailed investigations on the physiology of respiration, and the manufacture and effects of the four gases mentioned above. He showed that inhalation treatment might be safely carried out. An abstract of this work is printed in the "Considerations."

His great aim, however, was to found a public hospital where systematic treatment of disease by gases and the study of their properties might be carried out, and for some years he appealed to the public for funds. Though it was the time of the great war, he met with a generous response. The Faculty of the Edinburgh School, with Alexander Monro at their head, supported him. He had many friends, such as the Darwins, the Wedgwoods, the Edgeworths, Reynolds the philanthropist, the Rev. Samuel Parr, Astley Cooper, Lambton the Earl of Dartmouth, the Marquis of Lansdowne, Dundas and Matthew Boulton. He was able to publish a list of 200 subscribers in 1795, and the appeal went on till 1798, when he determined to commence. Watt again helped him materially by finding and recommending to him young Humphry Davy, a remarkably able chemist and scientific worker. Beddoes induced him to come to Bristol to act as superintendent of the proposed Institute, and Davy, writing to his mother from Beddoes's house in October, 1798, tells her that Beddoes had given up to him the whole of the business of the hospital and that he was planning how it should be carried on when opened. In November he writes that they are negotiating for a very suitable house in Dowry-square. This was taken, and they were soon ready to begin work on the gases already known and any others which were promising. He says elsewhere that he felt it his duty as superintendent to investigate nitrous oxide, but evidently disliked the job. John Davy, in his "Memoirs of the Life of Sir Humphry Davy," p. 45 and p. 52, adds that in the beginning of 1799 he took up his residence in a house in Dowry-square, which was provided with a laboratory, and fitted up for the purposes of the institution. "Here he began investigating the effect of gases in respiration. Of these, nitrous oxide was one of the first he experimented on. Its agency he found to be of a very novel and wonderful kind." The details of this work are given in two articles.

Details of the Experiments on Nitrous Oxide.

1. A paper by Humphry Davy, entitled "Researches chiefly concerning Nitrous Oxide," extends to 340 pages, and was published in June, 1800 in Nicholson's *Journal of Natural Philosophy*, and was reprinted in the third volume of his "Life and Works." In it he reports fully the experiments which he made personally on the production, analysis, and reactions of nitrous oxide, and some allied gases, and their effects when absorbed by plants or respired by men or animals. He aimed at finding out whether it was respirable, and, if so, what were its therapeutic powers, and whether, in the language of the Brunonian system, it was a stimulant or depressing. We have seen that Dr. Mitchill had announced that it was highly poisonous—in fact, the principle of contagion. Davy says that he had shown the fallacy of this before he came to Bristol ("Works," vol. iii., p. 269), but at first the gas could not be obtained in a state of purity and he was quite alive to the danger of any mixture with "nitrous gas." As a matter of fact he did have a nearly fatal accident with the latter, and another with "hydrocarbonate."

He tells us that early in March, 1799, he and two friends cautiously tried inhaling the impure gas well diluted with naturally unpleasant results. Early in April he obtained the gas pure by heating ammonium nitrate, and on the 11th he ventured on a single inhalation of the pure gas. As it caused no pain or spasm he proceeded to inhale it for half a minute from a silk bag on the 16th. On April 17th, in the presence of Dr. Beddoes, after closing his nostrils and exhausting the air from his lungs, he breathed from his silk bag four quarts of the pure nitrous oxide until he became practically unconscious. The excitement and pleasurable thrilling produced were the chief things noted, and as no ill-effects followed he inhaled it very frequently for some months, examining its effects on the pulse, temperature, digestion, &c., in endless ways. It could clearly be inhaled without harm, and it was not a depressant. He got many other persons to respire it, and 18 of these wrote down their sensations for him, including Coleridge, Southey, Priestley's son, and some physicians. Its exhilarating properties led to its being called "laughing gas," but very little notice was taken of its anæsthetic properties. Davy, however, on p. 276, does mention its power of stopping intense physical pain. For during an attack of severe toothache he repeatedly took it, causing the pain to disappear for the time. Dr. Rob. Kinglake, on p. 299, records that it suspended the powers of hearing, seeing, and feeling, and finally Davy writes, p. 329: "As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage in surgical operations in which no great effusion of blood takes place." I cannot explain his limiting phrases, but he clearly proposes it as an anæsthetic. The date is confirmed by a letter from him on this eventful April 17th to Davies Gilbert, where he says that he had this day discovered that the nitrous phosoxide is respirable when entirely freed from nitrous gas, and he had breathed it this day for seven minutes. He adds that Dr. Mitchill's theory is, of course, entirely overturned.

It was next tried as a remedy in various diseases, which was, of course, the object of the Institute. A few cases of nervous diseases were benefited, but in consumption both it and the other gases proved complete failures. The "Researches" were published, as we have said, in June, 1800, and in a rough draft of the preface he wrote: "These

experiments have been made since April, 1799, the period when I first breathed nitrous oxide. Ten months of incessant labour were employed in making them and three months in detailing them."

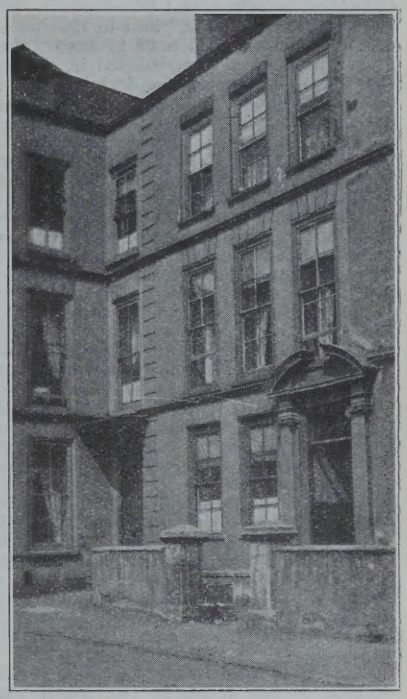
2. Dr. Beddoes's version is given in "A Notice of some Observations made at the Medical Pneumatic Institute," Longmans, May, 1799. He speaks most warmly of Davy's work, and adds that in their search for possible remedies Davy's attention was attracted to nitrous oxide, and that after making some experiments which showed that previous observers had been mistaken he (H. D.) had been led to respire it well diluted and in small quantities with depressing effects. When, however, it was obtained pure, Davy respired it freely in Beddoes's presence, and to his great astonishment showed extraordinary excitement and pleasure with no ill-results. He remarks that probably neither Priestley nor the Dutch chemists ever procured the gas so pure that it could be breathed with safety. It was easy enough to get a harmful gas, "as the author can attest from his own painful experience." He gives an abstract of the effects of inhalation by several of the healthy persons mentioned by Davy, noticing the loss of sensation by Kinglake and Morgan, and records the improvement effected in three paralytic patients. As to its use in phthisis he thinks that "the newly found gas may be regarded as a more powerful form of oxygen." On the whole he confirms Davy's claims and story up to May, 1799, and clearly thinks that no one had previously tested nitrous oxide narcosis.

For another eight months, then, Davy went on with his tests and observations before printing his "Researches," and suggesting it as an anæsthetic. In a final note to these "Researches" Beddoes adds a few observations of his own, but has nothing to say about the anæsthetic question. In detailing his own work Davy is careful to give many references to that of previous observers, and acknowledges his obligations to Beddoes. "In the conception of many experiments I have been aided by his conversation and advice," and he mentions some experiments of Beddoes, p. 197, and one suggested by him, p. 150.

Another volume of papers by Beddoes, Davy, and his fellow workers was published in 1799—viz., "Contributions to Physical and Mental Knowledge"—but nothing dealing with nitrous oxide appears in it. In January, 1801, Davy wrote from Dowry-square of the work going on at the Institute, but about that time he received the offer of an appointment at the Royal Institution in London, and left in March of that year. The Pneumatic Institute went on under Beddoes, John King, and J. E. Stock. Additional premises were taken on the Broad Quay in 1803, but the failure to obtain cures by inhalation led Beddoes to devote himself more to the teaching of preventive medicine (T. W. Jones, "Science Progress"). He died in 1808. Humphry Davy, as is well known, soon made very important discoveries in chemistry and electricity, and invented the miner's safety lamp in 1815. He rose to the highest rank among the scientists of the day, was made President of the Royal Society, and died in 1829.

Side view of the Institute, now 6 and 6A, Dowry-square.

It is an astonishing thing that after the power of nitrous oxide to destroy pain and its safety had been shown by elaborate and repeated experiments and its probable value as an anæsthetic in surgery had been pointed out by the most rising scientist of the time, practically no use was made of it for 45 years. Hickman, of Ludlow, about 1846, proved that operations on animals could be done painlessly under this gas or carbon dioxide, but no one in England or France would try it on human beings. However, the exciting effects of this "laughing gas" led to its being frequently inhaled as an amusing experiment at chemical lectures until, in 1844, Horace Wells, an American, after seeing it thus given, and noting that the person inhaling felt no pain if struck, insisted on having a tooth extracted under the gas, and forthwith employed it regularly in dentistry. Thus at last did the work of Davy and Beddoes bear fruit. If Davy had not purified it and had not popularised its use, Wells could not have introduced it into practice.



A view of 6 and 7, Dowry-square, the Institute being the corner house.

The House where the Experiments took Place.

We have now to inquire which was the house where this experimental testing of the gas took place. It is curious that doubts should have arisen and various sites been suggested. If we turn to the local directories of the time we find that the Institute and the names of the staff are given, but the house is left uncertain. In the "Bristol Directory" are these entries:—

1799 and 1800.—Hotwells Medical Pneumatic Institute. Physicians: T. Beddoes, M.D.; R. Kinglake, M.D.; P. Roget, M.D. Medical superintendent, H. Davy.

1801.—Hotwells Medical Pneumatic Institute. Physician, T. Beddoes; surgeon, J. King; medical superintendent, H. Davy.

1803.—Hotwells Medical Pneumatic Institute. Physician, T. Beddoes, M.D.; surgeon, J. King.

1805.—Medical Institution, Broad Quay and Hotwells. Physicians, T. Beddoes, J. E. Stock; surgeon, J. King.

Of the names here mentioned we may note that Peter Roget, author of "Thesaurus of English Words and Phrases," lived in Dowry-square; King, the surgeon, lived there, too, at No. 5, and Stock in Park-street, but where Kinglake resided is doubtful. However, he and Roget wrote down their experiences of inhalations, and Kinglake seems to have taken a large share in the investigations.

Stanley Hutton mentions that on March 21st, 1799, an advertisement appeared in the *Bristol Gazette and Public Advertizer* announcing the opening of the New Medical Institution. It says:—

"This institution is fixed at the upper end of Dowry-square, Hotwells, corner house. . . . It is intended, among other purposes, for treating diseases, hitherto found incurable, on a new plan. At present it is only ready for out-patients, and the

attendance of persons in consumption, asthma, dropsy, &c., which ordinary means have failed to remove, is desired. . . . Attendance will be given from 11 till 1 o'clock by Thomas Beddoes or Humphry Davy."

Joseph Cottle, the publisher, at this time a friend of Coleridge, Southey, and Wordsworth, published in 1837 his "Early Recollections," and in this he gives a long account of the Institute. On p. 29 he says "the house of the pneumatic institution was situated in Dowry-square, Hotwells; the house in the corner forming the north angle of the square." Thus Cottle and the advertisement tell us it was a corner house, and Cottle adds in the north angle. Now Dowry-square is a quadrangular area with buildings on three sides, and is part of a large open space which was probably once a common. The houses are fine specimens of early eighteenth century work built at a time when the Hotwells was a fashionable quarter—i.e., 1720 to 1750. They are practically unaltered, though now let out in tenements. On taking the bearings of the square, it turns out that one angle does practically point to the north (strictly north-north-west), and is occupied by a house with an L-shaped front. This house, now No. 6, is really the last of a row of lofty mansions forming the north-east side of the square. This house, too, runs back a long way. Its north-west side, unseen from the square, forms a façade of considerable size with nearly 20 windows facing the "Polygon" path up the hill to Clifton, and separated from it by the remains of a garden. Part of the block is now separated from the rest and is numbered 6A, but on each floor the loosely bricked-up doors and passages show the original plan of one house.

Quite recently, by the kindness of the owner, Mr. A. J. Mott, I was allowed to see the title deeds of the property which settle the question finally. In two distinct documents an abstract of title is given in almost the same words. They speak of all those two messuages, tenements, or dwelling-houses, Nos. 6 and 6A, formerly one dwelling-house standing in Dowry-square, and formerly in the occupation of Thomas Beddoes, M.D., and also the piece of ground or garden adjoining.

Thus it is quite clear that Dr. Beddoes was the tenant of this corner house in the north angle, the block now numbered 6 and 6A, formerly one house and garden. No. 6 by itself is far too small to provide rooms for experiments, a dispensary, and laboratories. It consists of two rooms and a closet on each of the five floors, and the Institute had, we know at one time 80 patients in attendance, and possibly eight or ten in-patients, according to a somewhat confused statement in Beddoes's "Notice." It was founded by an association of wealthy and influential people who wished that this experiment of the treatment of consumption and other diseases by the new gases should be carried out with every needful appliance and convenience. The combined block, with its doorways and passages now bricked up, did provide them with a compact and useful little hospital. No trace of any furnaces or stills can now be found on the premises. The garden mentioned in the "Researches" and in the deeds, though now partly built over, still opens into North Green-street or Polygon-lane.

Thus I think there can be no reasonable doubt that it was in the houses now numbered 6 and 6A, Dowry-square, that nitrous oxide was first obtained pure, and its properties were tested chemically and by inhalation, that this commenced in April, 1799, and that before June, 1800, Humphry Davy was able to recommend it as an anæsthetic in surgery after endless experiments. It appears to be the first gas to be suggested as an anæsthetic, and no one before Davy had ever ventured to experiment with and test this substance on account of its supposed deadly properties. He showed so thoroughly its harmless character and so popularised its use as an amusement that finally Horace Wells was led to employ it in dental operations in 1844. The great effort to find a cure for consumption was a failure, but indirectly it produced this and other valuable fruits.

INCOME-TAX ALLOWANCES FOR REPLACING CAR.

A.D. writes: "My four year old car which cost £270 is being replaced and an allowance of £80 is made on purchasing a new car. No depreciation claims have been made during the last years on the income-tax returns. Under the Finance Act, 1926, am I entitled to an allowance equivalent to the difference between the purchase and selling prices of the old car, or to an allowance equal to the difference between the selling price of the old car and the purchase price of a new car?"

How the allowance works in practice can be best seen by taking three illustrative cases in which the new car costs the same as, more than, or less than the original car respectively:—

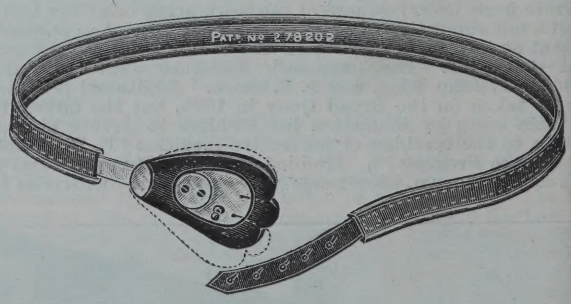
(*a*) Cost of original car £270, replaced by new car costing	£270
Allowed in part payment of new car	80
The amount to be charged against profits in the year of change is	£190
(*b*) If cost of new car is	£300
And allowance on old car is	80
The charge against profits would not be	£220
but would still be £270 less £80—i.e.	£190

The difference between £220 and £190 is a capital outlay not chargeable against profits.

(*c*) If cost of new car is	£250
And allowance on old car is	80
The charge against profits would be .. .. .. which is the expense of the renewal, there being no capital increase involved.	£170

THE DIGITRUSS.

THE accompanying illustration shows a form of truss devised by Mr. H. E. Cooper, of 162A, Adelaide-road, Brockley, London, S.E. 4, who has taken out a patent for it under the name of the "Digitruss." It has been designed to imitate the natural action of the hand and fingers when they are used to control a hernia, and the pad contains a light malleable metal plate fitted with a keyhole slot for horizontal and vertical adjustments. The plate terminates in three fingers which can be raised or depressed inde-



pendently so as to produce pressure where it is needed. The plate is separated from the patient's body by an india-rubber sponge pad, held in position by an india-rubber cover which can be slipped on and off. The pad is flat, soft, and resilient and is a satisfactory agent for applying pressure in the right place and without discomfort. It is claimed that the pad will automatically adjust itself to movements of the body in such a way that no understraps are required to keep it in position. It can be lowered or raised by loosening two screws in the locking plate.

From this description it should be evident that the Digitruss is an ingenious and convenient appliance.

ANÆSTHETICS AT THE SALPÊTRIÈRE.

IN a volume[1] recently issued from the Salpêtrière Hospital, Paris, there is a contribution from Dr. M. Boureau dealing with a series of 24,000 cases of general anæsthesia conducted by himself. The anæsthetics that he has employed were, except in some 160 cases, always either chloroform, ether, or ethyl chloride. Dr. Boureau's methods are as simple as his means, and he appears to find little use for complicated apparatus of any kind and to eschew nitrous oxide almost entirely. Nevertheless, his results, qua fatalities, have been good. He records three fatal cases of syncope, all with chloroform. His comments do not bring to light any facts or ideas which are new to anæsthetists in Great Britain except the pathetic plea that there should be a specialist in anæsthetics attached to every surgical service. This seems a quaint anachronism to issue from a great hospital.

An Address

ON THE

EDUCATION OF MEDICAL OFFICERS FOR SERVICE IN THE TROPICS.

Delivered at the International Continuation Course of the League of Nations, Nov. 24th, 1927,

BY ANDREW BALFOUR, C.B., C.M.G., M.D. EDIN., F.R.C.P. LOND. & EDIN.,

DIRECTOR, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

PART I.*—TROPICAL MEDICINE.

THERE has recently been published a lecture by an old-time and retired medical officer in a certain British Colony, a lecture which has been acclaimed by a local newspaper as a monument of wisdom. Its leading article commented with special approval on his statement that training medical officers in tropical medicine in this country was a mere waste of time and money. It referred to a two weeks' course, which happily nowhere exists, and showed itself profoundly ignorant on this as on other points, but it is sad to find a medical man with a record of long service in the tropics expressing an opinion so contrary to the teachings and practice of the great Sir Patrick Manson. True he need not be taken seriously, while no doubt there is truth in his contention that the best place to study tropical medicine, at least on the clinical side, is the ward of a good tropical hospital.

Let us, however, consider his futile argument a little in detail. His idea is that it is far better for a medical student after graduation to hold a resident hospital appointment in this country and then to proceed to the tropics, soundly grounded in general medicine and surgery, than for the same graduate to pass directly from his medical school to a school of tropical medicine from which he will fare foreign. No one will deny that, if it can be managed, the newly fledged medico should gain experience either in hospital or in private or dispensary practice before he takes up the study of tropical diseases, but it is well to remember the motto engraved on the clock face of the quadrangle of the medical buildings at the University of Edinburgh—*Ars longa, vita brevis.* Nowadays, after a six years' medical curriculum, a man is anxious to enter as soon as possible upon his life's work and to earn his livelihood, and very often he cannot afford the time necessary to gain what is undoubtedly much-needed experience.

But even supposing the desideratum of our reactionary colonial medical officer is fulfilled, what happens? His medical man, well equipped in ordinary essentials but blissfully ignorant of parasitology and of the symptomatology of tropical maladies—for these subjects are at the best inadequately dealt with in the crowded medical curriculum—proceeds abroad and promptly finds himself in a quandary. He encounters a case of malaria and, having heard something about ague, looks, but looks in vain, for a typical temperature curve and a hot-and-cold stage. Unable to make a proper blood examination, or at least to detect the malaria parasite in the blood, he begins, if he is wise, to doubt his diagnostic powers. If unwise he carries on, and it is at least possible that his patient also carries on to another world, proceeding from the ward feet first to the appointed cemetery.

I have chosen malaria as it is perhaps the most protean of all diseases and may simulate almost any complaint, but conversely other diseases may mimic malaria. Let us suppose that the medical officer encounters a case with rigors and a muddy complexion, a continued temperature, an irritable temper, night sweats, insomnia, and a pain in his right shoulder. There is an old history of malaria and there is nothing very definite about the symptoms. Ten to one he says to himself, "chronic malaria," and exhibits quinine. The patient does not improve. On the contrary, he gets worse, and then one day the doctor finds an ominous fullness in the right hypochondrium and realises, possibly too late, the real nature of the case. He has never before seen an example of hepatic abscess and does not know that it may follow a dysenteric infection so slight that it has been forgotten or perhaps has even passed unnoticed. He is not on the *qui vive* as he should be, he has not thought of amœbic hepatitis and its grave sequela, and, like many another physician, he has been caught napping. He and his patient are fortunate if recourse to emetine at this stage effects a cure. In all probability an operation will be necessary and the patient may swim for his life, as the saying goes.

I might multiply examples, but it is scarcely necessary, for happily there are few nowadays who share the amazing view of the gentleman I have cited. All those with a knowledge of the subject and a sane outlook on life will admit that, not only as regards liver abscess but in a host of other tropical maladies, forewarned is forearmed, and will agree that, with the facilities now existing, it is little short of criminal to send a medical man to practise in the tropics who has not received an adequate training in tropical pathology and parasitology combined with clinical instruction in the so-called diseases of hot climates.

While there can be no dubiety on this score, the best method of securing such adequate training remains a question for very careful consideration. It is true that here in London we believe that the course given by the School of Hygiene and Tropical Medicine meets most requirements very fairly well, and we are encouraged in that belief by the opinions expressed by some of our students now resident abroad and who are in a position to make an authoritative statement on the subject. At the same time, we are far from claiming that our curriculum approaches perfection. We recognise that it does not suit all needs and that it may, before very long, require modification. This is not surprising if we consider those for whom we have to cater. Presumably these do not greatly differ from the classes of students who attend any school of tropical medicine, though here perhaps we have a greater variety.

TYPES OF STUDENTS.

First and foremost there are the medical officers of the Colonial Medical Service, either men or women going abroad for the first time to take up appointments or medical officers who have served in the Colonies or Protectorates and who, for some reason or other, have not been through a course in tropical medicine. There are also those who think it well to take a refresher course when home on leave. Again, there are medical missionaries, some proceeding for the first time to the mission field, others back from it and anxious to be up to date. There are officers of the Indian Medical Service with very considerable practical experience in clinical work, but perhaps a trifle rusty in laboratory technique and not well versed in recent developments. There are medical officers of business companies, most of whom have usually served in the tropics, on plantations or elsewhere. There are medical officers of railways, occasionally there is the ship's surgeon, though he is not nearly so common as he should be, there is the laboratory and research worker anxious to brush up his knowledge or, it may be, acquiring for the first time an extended acquaintance with tropical pathology, entomology, helminthology, and protozoology. Not infrequently there is—to his credit be it spoken—the private practitioner in the tropics who, recognising his deficiencies, seeks to remedy them at his own charge, and, more rarely, the man going out to practise in the tropics who has the sense to appreciate the fact that he is about to be plunged into a new world

* Part II. will appear in a coming issue.

when he gets there and that, both for his own sake and that of his patients, it were well to get a grasp, and a scientific grasp, of certain fundamentals. Lastly we have the man who attends the course because he is interested in the subject and is a seeker after knowledge or because he thinks that some day or other he might like to go abroad and, finding that he has time at his disposal and the necessary funds, takes the opportunity of becoming familiar with one of the most fascinating branches of medical study and incidentally with those ancillary sciences on which tropical medicine is securely based.

You will admit we have plenty of variety here and yet, in the main, we need only consider two groups, those who have had practical experience of the tropics and those to whom the torrid zone is merely a name.

There can be no doubt that it is undesirable to unite these two groups into a single class, although it is true that some men may have learned little from their residence in the tropics, and it is also true that, while a man from the tropics may have good clinical experience, he may find himself at a disadvantage as compared with a student who has just completed his medical curriculum, whose laboratory knowledge is still fairly fresh, and who can also take more kindly to the rigours of a course of study and of its concomitant examinations.

A Short Course of Study.

Still, all things considered, it seems to me that the ideal thing (it is not, of course, always possible to attain the ideal), is to have a short course for those who have never been in the tropics, a course during which essentials can be hammered into them though, mark you, not a mere cram course, for that is fatal. It must be conducted on proper scientific lines and given that academic status which, I venture to think, is the basis of all sound medical training. At the same time it should concentrate on certain cardinal facts which the student simply must know. For example, after some preliminary training in microscopical technique, including instruction in the use of the dark field method, a point of considerable importance, he must be taught afresh how to examine the blood, both fresh and stained, how to recognise normal and abnormal cells, how to do blood counts, how to estimate hæmoglobin, how to avoid fallacies, and how to solve hæmatological puzzles. Blood changes met with in tropical pathology must be expounded to him and then, and not till then, he can turn his attention to malaria from the laboratory standpoint. It is strange how difficult it is to make the average student a competent malariologist in this respect. It is necessary to repeat the lesson again and again, both with the ordinary film and the thick film, but it is essential that he should obtain a thorough grasp of the subject and be in a position to say when what may be a parasite comes into his field of vision, "I am doubtful; therefore it is not malaria." When he reaches that stage there is hope for him.

I do not think, however desirable it may be, that it greatly matters whether or not he can in every case readily distinguish the species of parasite, save that he must, of course, know what a crescent portends, so long as he can recognise the plasmodium whether it be a small ring form, or a half-grown schizont, or a rosette, or a gametocyte. Such recognition must naturally be based on a clear conception of the protozoa, so while he is busy at malaria he must be familiarised with what we may call the elements of protozoology. There must also be a correlation of the blood findings with the clinical aspects of malaria so that, whether or not he can differentiate a quartan from a benign tertian or a malignant parasite, he must know what types of fever the different parasitic infections produce. He must also be thoroughly versed in the pathological anatomy of malaria and understand why and how acute malaria kills and why and how chronic malaria produces cachexia. It is also essential that he understands the relationship of blackwater fever to malaria and realises the blood changes in this condition.

Training in Malaria.

The more I see of training in tropical medicine, the more I delve into the literature, the more am I convinced that a sound knowledge of malaria is half the battle. This is not surprising when one remembers that malaria still remains the most common malady of hot climates and reflects that every year it slays some two million victims.

During his laboratory course on malaria the student should be given that clinical instruction which is all-important. He should see cases, he should take cases, he should, if at all possible, take the blood of cases and, whenever there is an opportunity, attend autopsies. It is far better to teach malaria from a patient than from the lecturer's desk, though, of course, theoretical instruction is required, and such instruction should be fully supplemented by class diagrams and museum specimens. One need not enter into the details of the clinical teaching, but perhaps mention should be made of the necessity of warning the student, as did Sir Patrick Manson, that every patient coming from the tropics with fever is not suffering from malaria, that indeed he very often is not a tropical case at all, and of impressing upon him, not only the protean character of malaria, but the fact that it often exists with, and may mask or be masked by, some other disease. If he gets these truths into his head something will have been accomplished, and if he also is made to realise that in the treatment of malignant malaria "time is of the essence of the contract," in other words, that the sooner the patient gets his quinine the better, then it is probable that some day or other a life will be saved which might otherwise have been lost. I would like to record my opinion that not only should there be clinics in the classroom but that the students should visit the wards. It is important that they should see cases seriously ill from malaria, and it is rarely that such patients can be brought to a classroom. Valuable lessons are furnished by malaria cases shivering and with chattering teeth in the cold stage, flushed and restless in the hot stage, or sweating profusely as the temperature falls. Nowadays, in this country coma will rarely be in evidence but, once seen, malaria coma is not easily forgotten. Those of us who accompanied Manson in his ward visits will recall how valuable were the lessons he taught on cases which could not be exhibited in a lecture theatre.

The instruction will naturally comprise an account of the method of infection, and a short introduction to entomology may be followed by a study of mosquitoes and more especially of the anophelines. For the class of student I have in mind I do not think it is necessary to go very deeply into the subject. I do not believe that the practice of mosquito dissection is essential. What is required is that the student should be able to recognise an adult anopheline, should know the habits of this family of mosquitoes, should be able to recognise anopheline eggs and larvæ, should understand the relationship of the female anopheles to malaria transmission, and should be familiar with those species which have been proved capable of acting as vectors of the malaria parasite. An outline of antimosquito measures to be supplemented during a course in tropical hygiene should also form part of the entomological instruction.

Scheme of Instruction.

It will be seen that, after some preliminary and general instruction, the idea is to take an important disease and to group round it, as it were, the teaching which is required for its full elucidation, considering it, therefore, from the purely clinical side, from the laboratory standpoint, and dealing with its relations to those sciences, hæmatology, protozoology, and entomology, with which it has close connexions.

It seems to me that this is the way to handle a short course of this kind, and there should be no difficulty in following out the notion in the case of all the big

protozoal diseases such as sleeping sickness, leishmaniasis, and, of very great importance, amœbic dysentery. In the same way when we come to the helminthic disorders, substitute helminthology for protozoology, bring in such entomology as is required as, for example, the rôle of the culicines, the simuliidæ, and the culicoides in filariasis, together with other necessary zoological information; snail hosts in schistosomiasis, fish in clonorchiasis, and so forth.

I am inclined to think that a couple of capable teachers, one on the clinical side, one on the laboratory side (and the latter, I admit, will not be easily found), with, of course, assistants and demonstrators, would be sufficient to ground the students properly, keeping, as I say, to essentials but not losing sight of the larger issues and forecasting, as it were, the longer and fuller course to which it is hoped the student will return after a sojourn in the tropics.

I think it likely that the idea will be anathema to some. A helminthologist will say, "I alone can teach helminthology properly," a protozoologist will emit a similar declaration regarding his subject, and an entomologist will probably voice a similar view respecting entomology. Yet for the specific purpose under consideration I doubt if this is true, although I admit there is something in another argument I have heard voiced—namely, that students with little or no knowledge of a subject are best taught by the professor himself while his assistants can, with advantage, take more advanced classes. However, this is scarcely the place to consider ways and means. The nature and scope of the course of study is what concerns us.

As I have said, the laboratory work, be it pathological or bacteriological, can be linked up with the diseases studied but, in addition, there must be some general instruction in methods and principles, for our experience shows that the majority of men coming direct from medical schools have either been inadequately trained in these subjects or have forgotten much that they have learned.

It would, I think, be hopeless to try to give detailed instruction in special subjects like tropical ophthalmology and dermatology, but a certain number of important eye and skin conditions should be selected and the lessons they convey clinically and from the bacteriological, mycological, protozoological, helminthological, and entomological aspects should be impressed upon the student. Naturally, the surgery of the tropics cannot be excluded. If the student knows nothing else he should know a good deal about tropical ulcers and how to treat them, while the surgery of liver abscess, of filariasis, and of vesical calculus should be taught him as far as it can be taught outside the tropic belt. Following this concentrated pabulum, which should be supplied along with ample wall diagrams and museum specimens, including models, which are most helpful, there should come a short course in tropical hygiene, somewhat on the lines of that which I hope to lay before you in my second lecture but lacking those sections which meet especially the needs of the medical officer of health as, for instance, public health administration and organisation and port health work. How much time should be devoted to this intensive training? I believe it could be got into three months without imposing undue hardship on teachers or students, and I very much doubt if anything shorter would serve the purpose, for there must be intervals, tutorial weeks we call them in our full course here, where the student gets a breather, has time to think, to ask questions, to consult the literature, to study in the museum. Otherwise, what Herbert Spencer said in his "Study of Sociology" will assuredly apply to him: "When a man's knowledge is not in order, the more of it he has, the greater will be his confusion."

I take it there would have to be an examination as it is unhappily the only method we at present possess of testing a man's knowledge, but I would be inclined to make it as practical as possible—laboratory work and viva voce. If there was any written part I would see that it took the form of an essay designed to make the student think for himself and more a continuance of the course of teaching than an instrument of torture.

Full Course of Study.

Passing now to the consideration of a training designed on a more liberal scale for those who, as the saying is, have "lived under the palm trees," I think I cannot do better in the first instance than outline the course of study at present pursued at the London School of Hygiene and Tropical Medicine.† This course covers 20 weeks, including the two class examinations, and one of its features is the presence of those tutorial weeks of which mention has already been made. A very considerable time is devoted to pathology and bacteriology. This includes instruction in the use of the microscope and its accessories, the study of the blood, both normal and abnormal, and, amongst other things, the dissection of mosquitoes. I think it should also include the dissection of ticks, or perhaps I should say their examination for spirochætes.

Entomology, protozoology, and helminthology receive due attention, both in the laboratory and classroom. Reference to the school prospectus will show the comparatively large amount of time devoted to clinical demonstrations which are conducted throughout the tutorial weeks and it will be noted that eight hours are occupied by lectures designed to give the student some account of recent advances in tropical medicine. This time, if desired, can to some extent be utilised for a revision prior to examination. A certain amount of biochemistry is included and a few lectures deal with the subject of poisonous plants in the tropics. Visiting lecturers deal with various subjects, amongst them epidemiology, dermatology, ophthalmology, mycology, the surgery of the tropics, and dental surgery from the standpoint of medical men far removed from dental help. Tropical hygiene will be considered separately, together with port and ship hygiene, in my second lecture.

Here, then, we have a curriculum covering a wide field and designed to give the student a fairly comprehensive view of medicine in the tropics. It also should, and I think does, indicate lines of further study. If time could only be found for it I believe a most useful lecture would be one on the literature of the subject dealing with books and journals, although it is true that any student with an inquiring mind and a discerning eye will soon discover from the invaluable *Tropical Diseases Bulletin* on which pages it were best to browse.

It would be wearisome and probably unprofitable to consider details of the teaching under the various headings I have mentioned, but there are a few points which, I think, may be touched upon with advantage.

Some Details of the Curriculum.

Let us take the clinical work first of all. In addition to the lectures on various maladies it is, I am persuaded, of the utmost value to have a discourse on the diagnosis of fevers in the tropics—in other words, an account of a survey which, somewhat in the fashion of a synoptic table, will, by a process of exclusion, eventually enable the physician to come to a correct conclusion so far, of course, as the vagaries of disease and the limitations of clinical and laboratory tests permit of finality being reached. The kind of thing I mean may be found in the "Memoranda on Medical Diseases" published by the War Office, and entitled "Fevers in the East." It is founded on a paper by Colonel D. W. Sutherland, of the Indian Medical Service, which proved most useful to many workers both at the bedside and in the laboratory, and to which students should be referred, being given, of

† A diagram setting out the curriculum is given in the published prospectus and calendar of the Division of Tropical Medicine and Hygiene. The graph shows at a glance the arrangement of the curriculum, including the tutorial weeks, and indicates the allotment of times to the various subjects in which instruction is given.

course, at the same time such new information as may have accumulated. I have already mentioned the usefulness of models. Those supplementing the clinical lectures are specially valuable, and an effort should be made to secure representations of tropical maladies in coloured races as, for example, the excellent series of the Amsterdam School.

Intravenous therapy is nowadays so important in tropical practice that the student should be carefully instructed in the technique. I should think it might be possible to have a model of an arm constructed on which he could practise though, so far as I know, such a desideratum has not yet been evolved. I am inclined to think that one lecture and demonstration on the chemotherapy of tropical diseases would serve a useful purpose, the subject being dealt with on broad lines. There is the question of the care of drugs in the tropics, their deterioration, certain peculiarities of action under tropical conditions as, for instance, the severe effects sometimes produced by ordinary doses of castor oil, the mode of action of some of the newer remedies (why is emetine efficacious in two such widely different conditions as amœbic dysentery and schistosomiasis ?), antidotes in what we may call therapeutic poisoning (sodium thiosulphate as a remedy for poisoning by some of the heavy metals), and so forth. A few words also on protein therapy would not be out of place.

In the case of surgery an account of the care and maintenance of surgical equipment, both in the dry and the moist tropics, would certainly appear to be indicated. A man who does not know how to look after rubber utensils is likely to be mulcted heavily in his pocket before he gains the necessary experience.

Some instruction in dental surgery is obviously desirable, considering how often medical men in the tropics are called upon to do dental work.

Here we pay particular attention to dermatology and ophthalmology, and rightly so, for skin diseases and diseases of the eye bulk very largely in tropical practice. They must be taught by specialists in these subjects, and their study well repays the time devoted to them.

The medical officer in the tropics is so often called upon to combine the duties of doctor and nurse that it might be well to give him a few hints on the nursing of certain diseases under tropical conditions. At any rate, he should be referred to the section on this question in Byam and Archibald's "Practice of Medicine in the Tropics."

There is not, perhaps, much to be said about those subjects which are chiefly taught in the laboratory.

The Laboratory Subjects.

Hæmatology has already been mentioned, but I would like here to insist on the necessity of making the student thoroughly familiar with both the healthy and the infected fresh blood film. Occasions will arise, perhaps not infrequently, when the medical officer will have to diagnose a case of fever and yet have no facilities for staining a blood film. Now I know from sad experience that nothing is more difficult than to diagnose accurately the conditions you see in the fresh blood. There are Maragliano bodies which would deceive the very elect, there are not infrequently appearances simulating malaria pigment while, without considerable experience, it takes a courageous and honest man to lay his hand on his heart and say, "This is undoubtedly a small ring form of the malaria parasite." The student should always examine the same blood fresh and stained, and indeed it is not a bad thing, when the scrutiny of the fresh blood is completed, to make a dry film of it, stain it, and examine it. The result is sometimes surprising and an excellent corrective to any tendency towards complacency with one's status as a hæmatologist and parasitologist.

The advanced student may with advantage practise vital staining of the blood. It is of special service in the absence of a dark field when searching for spirochætes.

The pathology of the various diseases will be taught along the usual lines, but I may say that, in a course of this kind where, as a rule, men have for some time been divorced from histological studies, it is very advisable to give them an opportunity of comparing the normal with the abnormal. In the study of malarial tissues this is specially desirable, for pigment is often a difficulty. It is not always an easy matter to distinguish true malarial pigment from other pigments, some of which may have no pathological significance.

Further, I believe that a most interesting and useful dissertation could be framed on fallacies and puzzles in tropical histopathology, nearly if not quite as informative as a similar discourse on blood examination. To cite one case only, it is very necessary that, in Levaditi sections, appearances closely simulating spirochætes should not be mistaken for these parasites.

Where bacteriology is concerned important questions of technique arise. The student must know how to surmount some of the difficulties which face the laboratory worker in the tropics, difficulties due to heat, to dust, to the abundance of aerial moulds, to the deterioration of glassware, and to various other causes which it would take too long to list but which, if he is not warned about them, will assuredly cause him considerable vexation and loss of time.

The importance of mycological infections in the tropics must not be overlooked and, though it may be impossible, as well as unnecessary, to produce mycologists, students should be familiar with the technique for demonstrating fungi, whether in a skin lesion or in a general tissue infection like mycetoma. A few systematic lectures on the tropical mycoses constitute a separate item in the course at this school.

I feel a little diffidence in attempting to say something about entomology, helminthology, and protozoology for, though I am to a certain extent familiar with all three subjects, I have had very little experience in teaching them and they are highly specialised. It is, however, clear that in each case it is necessary to give some general instruction and also, I think, to deal with nomenclature. An explanation of the terms used and of their derivation cannot fail to be helpful. It fixes the meaning in the student's mind and prevents the acquisition of that "parrot" knowledge which is so common and so distressing. In most instances the correct understanding of a scientific term throws light on the reason for its use and is a real aid in classification. Sometimes it is specially illuminating, as in the case of the word "anopheles," even though originally the term may have been employed in a sense different from that which it can now be made to serve.

When it can be arranged, it is well to give practical instruction first of all upon some typical form which will emphasise the character of a group or family. Thus in entomology a study of the cockroach, not in itself a specially harmful creature, but a typical insect of convenient size, serves the purpose. In protozoology the amœba provides a useful preliminary lesson while, if in helminthology no single worm may serve the purpose, yet the Ascaris of the horse may be taken as a type of the Phylum, Nemathelmia, and some large fluke or cestode will afford material for demonstrating the characters of the Phylum, Platyhelmia.

I need say nothing about the detailed teaching of the three subjects save that it should be as practical as possible and must perforce be largely limited to a consideration of insects, worms, and protozoa of real importance in tropical pathology and that, in the case of entomology, it is desirable to direct attention to insects which are destructive to stores, food, and equipment.

Ophidiology, the scientific study of snakes, must have a place in the course but need not be extensively pursued while, in addition to the venomous snakes, some attention should be directed to other noxious animals such as poisonous spiders and centipedes. It is also advantageous for the student to know something about poisonous fish, both those which

inflict poisoned wounds and those which cannot be eaten with impunity.

This leads me to say a word or two about poisonous plants. There can be no doubt that this subject should not be neglected. A few lectures upon those, the ill-effects of which are most commonly encountered in the tropics, will suffice and should be supplemented by the exhibition of specimens either dried or preserved in formalin or spirit.

Epidemiology and Biochemistry.

We include a little epidemiology in the course on tropical medicine, though perhaps it should properly be regarded as part of the hygiene course. It is not easy to teach such a large and complicated subject when time is limited, but I think it should not be altogether ignored. Useful lessons can be taught from a consideration of the geographical distribution of tropical diseases. Thus the fact that kala-azar is unknown in Mauritius and the West Indies may be employed to show how certain diseases are limited to certain places owing to the presence of a specific intermediate host in such localities; thus the existence of at least two varieties of typhus fever in the tropics and subtropics, the one louse-borne, the other of undetermined ætiology, will indicate the necessity for further research in this direction; thus the absence of malaria in certain districts where apparently it should be present will indicate limitations in our present knowledge. Again there is the influence of climatic conditions in such diseases as cholera and small-pox. Yet again the disappearance of yellow fever from certain West Indian islands where no preventive measures have been taken will raise questions of immunity and suggest a solution along the lines of epidemiological inquiry instituted by Topley and Greenwood in the case of mice colonies. I might easily multiply examples but these must serve.

Lastly, there is biochemistry. If, as has been said, "the future is to the biochemist," then certainly the biochemical aspect of tropical medicine cannot be disregarded. Its significance in the deficiency diseases, scurvy, beri-beri, and pellagra must be emphasised. In some parts of the tropics diabetes mellitus is a most important malady and in others nephritis is responsible for much morbidity and mortality. These pathological states can only be properly understood if their biochemical relations are fully appreciated.

Jaundice, as encountered in yellow fever, malaria, and many other conditions, cannot be explained save on a biochemical basis. There are certain tests with which the student ought to be familiar. Some of the more simple he should himself be able to apply if he is to play the part of a scientific physician and diagnose and treat his cases on satisfactory lines. It is not perhaps necessary that he should undergo a laboratory training in such tests, but they can be demonstrated to him and their significance explained, while he can be told where best to look for further information.

Length of Course and Examinations.

I have outlined briefly and imperfectly the kind of curriculum which I believe will benefit the serious student of tropical medicine. It cannot be compressed into less than 19 weeks of arduous study, and it were well if a somewhat longer time could be devoted to it, especially if it is intended to be a diploma course. I take it that, to justify their existence, examinations should be regarded as an integral part of scientific training. Hence I touch upon them here. We have two school examinations, the first on entomology, helminthology, and protozoology, the second concerned with some or all of the other subjects of the curriculum. The first consists of a written and a practical test, the second comprises the answering of set papers, practical work, and oral examination. It ought also to comprise a clinical in the wards or on patients but, owing to the fact that it is followed by a diploma examination and that the amount of clinical material is limited, this has at present most unfortunately to be omitted. The examiners do their best with models, illustrations, and museum specimens, but I admit that here is a hiatus which should, and I hope soon will, disappear. The standard has recently been raised but, even so, we find that only a few students fail and some of them doubtless benefit from the ordeal quite apart from obtaining a certificate of proficiency. I recall one very useful lesson which a diploma examination inculcated. Blood films containing *Acanthocheilonema perstans* were set for microscopical examination. A great many students never thought of making a scrutiny with the low power when they would almost certainly have recognised the infection. They were content to examine with the ordinary high power or the oil immersion. Naturally enough perhaps they failed to come across filariæ, for the number of embryos per film was limited. Had they been content to state that they could find nothing pathological or perhaps to hint at an eosinophilia, no great harm would have been done, but alas, finding nothing, they let their imaginations run riot and some discovered malaria parasites and some trypanosomes, a most serious state of affairs which necessitated the rejection of a considerable number of candidates. Rightly so, for in the tropics such conclusions might easily lead to very serious results. Imagine the Governor of an African colony sent home suffering from an imaginary, incipient sleeping sickness!

Two other points about the course, and I have done. It is, I think, very advisable to take advantage of the presence of any distinguished authority and get him to address the class. This breaks the routine, interests the students in a personality, and gives them an opportunity of hearing a subject discussed, possibly from a particular point of view, by someone who has shed light upon it.

Lastly, the cinematograph film can be used with good effect and so, in the museum, can the graphic and orderly method of exhibit to which tropical medicine lends itself so admirably. Such, then, are the principles and methods of training which seem to me well calculated to fit the medical officer for work in the tropics and which should stand him in good stead even when, far from help, he has to rely upon himself and upon the knowledge he has gained during his period of study. Yet let it be remembered that, even if the method be sound, much depends on the spirit infused into the teaching and on the ideal set before the student. Mere cramming is, as I have said, fatal. There must be an honest attempt at scientific grounding, an effort to interest as well as to instruct, a desire to impart that wider view and loftier aim which is perhaps best expressed in the words of the poet, George Herbert:

> "Who aimeth at the sky
> Shoots higher far than he who means a tree"

The Future
OF
MEDICAL PRACTICE IN ENGLAND.

By SOMERVILLE HASTINGS, M.S. Lond., F.R.C.S. Eng.,
SURGEON IN CHARGE OF THE EAR AND THROAT DEPARTMENT, MIDDLESEX HOSPITAL.

I THINK it will be generally admitted that no profession has seen greater changes during the last half century than our own. During this period the science of medicine has rapidly advanced, and changes in the organisation of the profession have naturally followed. The general practitioner of the past was not only physician, surgeon, apothecary, and accoucher, but also sanitary and public health adviser as well.

But during the last 50 years, at a rapidly increasing rate, one branch of medicine after another has been partially or completely withdrawn from the ken of the general practitioner. Sanitation and public health

are now dealt with exclusively by the medical officer of health; indeed, so little is the average practitioner concerned with preventive medicine that he is almost liable to forget the existence of this most important branch of his science. The diagnosis of notifiable infectious disease is still the business of the general practitioner, but directly removal to the isolation hospital is decided upon, he sees and hears no more of his patient. In some degree the same is true of tuberculosis, excepting that even the diagnosis of this disease takes place to an ever-increasing extent in the tuberculosis dispensaries. Both the diagnosis and treatment of venereal disease are now largely carried out at clinics especially instituted for this purpose, and I have been told by practitioners that they now rarely see a case of venereal disease in its early stages, although, of course, syphilis in its tertiary form is still cropping up fairly frequently. School clinics are now treating a good many of the chronic affections of childhood, previously dealt with by the practitioner or hospital or not at all, and the maternity and child welfare centres, although not originally intended for the treatment of diseased conditions, do in actual practice give treatment to many cases that would otherwise come to the general practitioner. In some districts a very large percentage of children are born within the walls of the municipal maternity hospital. "There are no fewer than 17 departments, spheres, or directions of clinical activity for which provision is made in this sectional way under the auspices of local authorities. Some of these cover an extensive field of medicine."[1] The treatment of the more serious mental diseases has been lost to the practitioner for many years, but few will, I think, regret this loss.

The appalling housing conditions, not only in towns but in many country districts as well, and the increasing complexity of modern methods, make the need for institutional treatment of the sick much greater than previously. Hospital beds are therefore rarely empty, and the poor-law infirmaries are taking more acute and subacute cases, while not a few of them have become staffed and equipped like the large general hospitals. But in very few hospitals or infirmaries does the practitioner retain any contact with his patient when once he has passed within their doors, nor is his doctor informed of the diagnosis made or treatment received when he passes out again.

A Continuing Process.

In these and other ways, then, during the last 40 or 50 years, the scope of the general practitioner has been continually narrowed and confined by public or semi-public provision for the treatment of an increasing number of diseases without his aid. Now this process is bound to continue for two reasons: first, because it is part of the spirit of the age to provide for its needs by collective action; and secondly, because, in spite of some defects with which I will deal later, the public provision for sickness already instituted has undoubtedly made for the general good.

Thirty-five years ago 1 person in 7 died of tuberculosis in England and Wales; to-day only 1 in 14 so dies. During the last 20 years (1905–1925) the infantile mortality-rate has fallen from 128 to 75 for 1000 births. Few people will deny that the public provision made has had a good deal to do with these beneficial results. In connexion with venereal disease the effects of State interference have been even more striking. Between 1920 and 1926 the number of new cases reporting at the clinics fell from 42,805 to 22,550 in the case of syphilis, and from 40,284 to 35,052 in the case of gonorrhœa. These, like many other figures, may possibly be misleading, but no one in active practice can, I think, doubt that syphilis is decreasing. But perhaps the best results of all are to be seen in connexion with the treatment of school-children. To take one disease only, Sir George Newman, as Chief Medical Officer of the Board of Education, in his annual report of 1923, tells us that, as the result of preventive and curative treatment, the percentage of children found on routine inspection in London with defective hearing has, during the last ten years been halved, and that in Cambridge and Exeter the results have been even more striking.

As I said before, I maintain that this process of robbing the general practitioner of clinical material is bound to continue and increase. The hospitals are constantly appealing for further extension of bed capacity, and not only do their long and increasing waiting lists support this appeal, but the Voluntary Hospitals Commission recently recommended that another two million pounds of public money should be given to the voluntary hospitals to equip more beds. The improved facilities for treatment in many poor-law infirmaries are enabling them to take many more acute cases which were previously treated at home, and now the Ministry of Health is inviting representatives of the poor-law and general hospitals to come together to discuss, among other things, whether the medical and surgical staffs of the hospitals cannot undertake the charge of cases in the poor-law infirmaries. This is undoubtedly all to the good from some points of view, but it will, nevertheless, tend to rob the general practitioner of a considerable amount of important and interesting clinical material. And now demands are being made for still further provision for certain classes of persons and certain types of disease. A very strong case can be made for the provision of similar inspection and treatment for the *pre-school* child to that accorded to the child of school age. It is truly pointed out that when children arrive at school for the first time the mischief is often already done and cannot be undone, and their efficiency for the rest of their life is impaired in consequence, and legislation cannot be long delayed in connexion with these young children. On the other hand, an equally strong case can be made for the adolescents between 14 and 16, for whom no public medical provision now exists. These children are, as a rule, earning little, and cannot pay for medical attention privately, and thus the good work done in the schools may readily be made of no account. The maternal mortality at childbirth, amounting to nearly 3000 annually, which has not markedly changed for some 25 years, is causing much public anxiety. What amelioratory measures will ultimately be adopted is not yet clear, but it seems not improbable that the public may demand a vast increase in maternity homes to be staffed exclusively by practitioners of special experience. There is also a demand in some quarters for a national campaign against cancer. Public cancer clinics have been fairly successful abroad, and may at any time be introduced into this country. There is a strong feeling also in some quarters that efficient treatment should be provided for orthopædic cases and for heart disease in children. Further public provision for the prevention and treatment of disease is inevitable, and if carried out in the same way in the future as in the past, is bound to still further rob the general practitioner of much of the variety and interest of his work.

Incoördination of Public Institutions.

Our public provision for the sick may be looked upon as a series of watertight compartments having no communication with each other. If the right sort of person with the right sort of disease happens to fall into the right compartment the treatment obtained is generally good, but there is little to guide him into the right compartment, and nothing to do for him if he happens to fall into the wrong. A good example of the complete lack of coördination between the different schemes for provision for the sick came before my notice recently. Eighty-three of the patients in a large county sanatorium for tuberculosis are children. Of these only three showed definite signs and symptoms of tuberculosis after careful observation lasting over many weeks. Most of the others were classified as "indefinite for observation." But 58 per cent. of these children were found to be suffering

[1] Leading article in Brit. Med. Jour., June 11th, 1927.

from septic tonsils and adenoids. Unfortunately, however, in all but one case all attempts to get these tonsils and adenoids removed have so far failed. "Tuberculosis" these children have been diagnosed, and tuberculosis they must remain for the rest of the chapter, and so they will have to stay at the sanatorium for anything up to 18 months at the cost of the ratepayers.

When the Ministry of Health was created, it was hoped that it would serve to coördinate all the various services dealing with public health. Unfortunately, however, we have had, so far, but one Minister of Health (the first) who could be expected to have any knowledge or experience in health matters, the other Ministers of Health being clearly appointed for their skill in getting houses built or preventing their being built, according to the desire at the moment of the Government in power. Moreover, at best the Ministry of Health can only act as a coördinating agency at the centre, and what is needed is coördination at the periphery as well, and no one can do this effectually but the general practitioner. It seems to me that without him increasing incoördination is bound to occur, as more and more of his patients are taken from him and brought under the care of the State. I look upon the general practitioner as an essential part of the equipment of every family, whether rich or poor, not only to serve as guide, philosopher, and friend, but as registrar of events of medical importance as well. Now if the practitioner is excluded from, and knows nothing of, some of the most important phases in the medical history of his patients, it will be impossible for him to take his part as he should, and I have no doubt that the absence of the natural liaison officer is the main cause of the imperfect success of some of our public health schemes.

Beyond question, such is the increasing complexity of medical science, an even larger amount of treatment will have to be undertaken by specialists, and a good deal of it within the walls of hospitals or similar institutions; but unless the general practitioner's business takes him to these institutions to coöperate with the specialists in the treatment of his patients, he cannot possibly keep his medicine up to date and know what to expect from each specialist line of treatment. From the specialist's point of view also it must be admitted that intimate contact with the man who sees all sides of medical practice is going to lessen that narrowness of outlook which is inseparable from specialisation. In my own experience, at any rate, it is often a much more difficult problem to make a diagnosis and decide on the best line of treatment for a given patient than to actually carry it out. The general practitioner, to whose province this must mainly fall, must, therefore, always be the most important person in the medical hegemony, and any scheme of medical service that fails to take this into account is of necessity foredoomed to failure. Equally, then, from the point of view of the faculty and the public it is essential that the general practitioner should take his proper place in the public medical service of the future.

A Public Medical Service.

The provision by the State of some form of public medical service within the next few years seems to me inevitable. Whenever I have had occasion to speak of it to a lay audience the proposal has been universally applauded, and other people with much greater experience as political speakers have told me the same. We may look upon some form of State medical service, then, as certain within the next few years. Two courses are open to our profession. It may resist the inevitable till the last moment, have some ill-digested and imperfect scheme thrust upon it, like the National Health Insurance Act, or it may profit by the experience of the past and seek to mould public opinion so that when the new order comes the general practitioner may have an honoured place in it as the natural centre around which the whole scheme revolves.

HÆMANGIOMA.

By J. J. M. SHAW, M.D., F.R.C.S. Edin.,
SURGEON, LEITH HOSPITAL; ASSISTANT SURGEON, ROYAL INFIRMARY, EDINBURGH; LATE SURGEON TO QUEEN'S HOSPITAL FOR FACIAL INJURIES, SIDCUP, KENT.

This group of tumours presents many points of interest in ætiology, in clinical manifestation, and in the problems of treatment. They are the commonest tumours of childhood, and are not rare in adult life. In many cases the superficial tissues are involved, but in spite of the consequent facilities for observation the classifications of the past have been in the main purely descriptive, and have embraced overlapping pathological and anatomical features. This confusion is usually increased in two ways. The first is the inclusion under the group name of "hæmangioma" of varicosities and aneurysmal dilatations of ordinary blood-vessels. Adami[1] has insisted on the need for a sharp line of demarcation between vascular enlargements of this type and the true tumours which we are now considering, which arise from unipotent angioblastic cells. The second and subsidiary source of error lies in the use of the term "nævus" in describing the hæmangiomata and melanomata alike. The word should be restricted to the latter group.

The chief purpose of this communication is to discuss a general plan of treatment upon the division of the tumour group into its three histological types, which are also capable of clinical distinction—the capillary, the compact, and the cavernous. This is the classification which has been advanced by Fraser,[2] and his definition of a hæmangioma may be accepted—namely, "a tumour in which there is an actual new formation of vessels, or proliferation of the vessel walls." The definition and classification will be considered more fully after a brief consideration of some of the general features of the condition.

Distribution.

In most cases a definite hereditary factor can be recognised. There is no noticeable difference in incidence among the different races of mankind, although naturally the lesions are less readily observable in dark-skinned peoples. The references in literature are very scanty, but there is reason to believe that the tumours on the whole are rarer among animals than in the human subject. Women are more often affected than men. One half of the body, limbs and trunk, may be affected—hæmangioma unius lateralis. One limb may be involved, or the zone of distribution of one nerve, such as the trigeminal, may be mapped out with varying degrees of accuracy. The smaller tumours, varying from the size of a florin to a minute speck, are common on the face and around the shoulders and buttocks. Several anatomically unrelated tumours may be present in the same individual, and bilateral symmetry is extremely rare. The gradations of size range from a growth which may necessitate the sacrifice of a limb, or, on the face, may render the unfortunate subject a source of misery to himself, or of repulsion to his fellows, to an almost invisible point of discoloration which may disappear spontaneously, or be cured at once by the touch of a fine electro-cautery.

The skin, mucous membrane, subcutaneous tissue, or any of the deeper structures, including bone, may be implicated, either alone or in conjunction. A considerable number of cases have been recorded in the larynx. In the rare instances of involvement of the heart, brain, and lungs the tumour has usually been fatal.

Extension and Retrogression.

The tumour is usually present at birth or becomes visible in early infancy. Its nature may be evident from the outset or it may look bluish, like a recent bruise, the true nature of the condition manifesting itself gradually. It may remain constant in size, may grow, pari passu, with the child, or may extend rapidly. Sometimes a definite infiltration of the

adjacent structures, including bone, takes place at an early stage. In more exceptional cases, and usually at a later age, metastases occur along routes which are at present unknown.[3 4] Retrogression is also shown in a considerable number of cases; thus a

FIG. 1.

small port-wine stain, belonging to the capillary group, may completely disappear. In other cases the regressive change is shown only by the waning of the bright purple or red to a tint which is scarcely distinguishable from the surrounding skin. This process of spontaneous cure is due to a progressive diminution of the blood-supply of the tumour area, which is effected, as Ribbert[5] first demonstrated, by a stenosis of the entering blood-vessels, and also by an increase of fibrous tissue in the stroma, especially at the periphery, where, in tissues other than skin, a definite thin capsule is often found. It is common for this retrogression to accelerate markedly at the period of first or second dentition or at puberty. The clinical features are discussed in great detail in the classical and masterly monograph of John Duncan[6] on the angiomata.

Ætiology and Histopathology.

Ribbert made an exhaustive study of the development of the hæmangiomata, and was the first to describe their origin from angioblastic embryonic tissue. He strongly opposed the view, prevalent in his time, that the tumours arose from pre-existing blood-vessels which had functioned as such. Fraser[2] gives in detail the results of his observations on the histology of the various forms of the hæmangiomata and on their common origin. His new classification is based upon the histopathology, and is simple, precise, and comprehensive. It has the additional advantage that certain broad lines of treatment can be laid down for the three varieties of the tumour, as these are clinically distinguishable. The following brief descriptions are based upon Fraser's work.

Capillary Hæmangiomata.—The first evidence of the formation of the normal vessels of the blood vascular system is in the vascular layer of the embryo, where groups of specialised endothelial cells, the blood island of Pander, proliferate and become finely vacuolated. Fusion between contiguous groups takes place, their fine channels become united, and give rise to a delicate capillary network which, in time, forms the capillaries and lining of the larger blood-vessels as a continuous blood circulatory system. The origin of the hæmangiomata can be traced to the failure of certain of the cells, or cell groups, to establish contact with the developing network. Such cells proliferate and become vacuolated, as do the others, but in their disjoined state do not proceed beyond the stage of a mesh of minute irregular blind channels, through which the blood of the general circulation does not pass. The lumina of the tumour of this type are either empty or contain a few immature or degenerate corpuscular elements. Such is the capillary hæmangioma (Fig. 5A), which may grow rapidly as a tumour and may vary in size, as seen superficially, from the minute "araneus" or speck of looped capillaries on the face, to the large, flat, port-wine stain. The so-called "de Morgan" spots are probably "rests" of such endothelial cells which do not proliferate until late in life.

Compact Hæmangiomata.—Proliferation may become more intense in the cells which form the walls of the fine pseudo-capillaries, and give rise to perivascular and endovascular thickening. The result is the formation of a solid mass of cells in which the lumina are no longer visible. Such is the compact hæmangioma (Fig. 5B). This is usually a solid subcutaneous swelling, closely resembling a lipoma.

Cavernous Hæmangiomata.—The third type results from the establishment of a connexion between the general circulation and the fine channels of the capillary type of tumour. The capillary tubules become distended, the walls break down further, and pools and channels of normal blood are found in the irregular spaces which are still lined by endothelium. Many of the spaces are culs-de-sac, in which the circulation is sluggish, and thrombosis may take place, especially in the limbs. Such is the cavernous hæmangioma (Fig. 5C), which may be found at birth or may affect a capillary tumour of long standing, the change being initiated in some instances by trauma or ulceration.

The delicate stroma of the capillary and compact tumours receives a septal blood-supply from normal vessels which are only slightly increased in number and size. The entrant vessels in the cavernous type are usually increased in both respects, but not markedly. Thus, while an incision within the cavernous tumour zone may cause an alarming diffuse hæmorrhage, an approach to the tumour from without, with exposure and double ligature of

FIG. 3.

Hæmangioma unius lateras. Capillary type on abdomen where it is arrested abruptly at midline. Large breaking down areas of endothelial tissue, and endothelial lined spaces containing thrombi in limbs. Excision of protuberant masses on leg. Further treatment deferred until after puberty in expectation of some regression.

the vessels before they enter the tumour mass, occasions only slightly more hæmorrhage than the extirpation of a fibroma or other simple tumour. The exposure of the entering vessels is readily effected in most situations by traction upon the tumour mass after the superficial circumferential incision. The entering vessels can then be picked up individually, as are the intercostal branches in removal of the pectoral muscle, in the operation for carcinoma of the breast.

If the surface of a cavernous angioma becomes broken a persistent chronic ulceration, with occasional severe hæmorrhage, may be set up, and an epithelioma may develop in such an area of chronic irritation. Rarely a true infiltrating endothelioma, or even a sarcoma, may appear at the site of a hæmangioma. A cavernous tumour in a viscus such as the liver is well known; it consists of a sponge-like reticulum, in the spaces of which normal blood circulates. When the skin and subcutaneous tissues are involved, the "mixed angioma" of the old classifications, the altered skin is raised, bluish, and nodular, and bleeds very freely when incised. When a cavernous tumour is entirely subcutaneous, or there is a subcutaneous spread from an area in which the skin is also involved, there is an elevation of the skin, combined with sagging of the part as a whole, and on pressure the part seems abnormally soft. Occasionally a diffuse pulsation can be felt.

Cavernous hæmangioma of face. A, Condition prior to operation, showing several nodules at which hæmorrhage had occurred. B, Showing result of complete excision and repair by forehead pedicle flap. Searing of lower eyelid by cautery.

Treatment.

The age of the patient, the situation, size and type of the tumour, the degree of disablement or disfigurement, and the economic and psychic effects on the particular individual, must all be considered. Since spontaneous arrest and cure may occur up to the period of adolescence, it is inadvisable to embark upon drastic treatment for the larger tumours in children, unless they are extending rapidly or are in a situation, such as the orbital region, in which even slight extension may be dangerous. The solid tumours do not retrogress, and therefore the question of age does not arise. Experience shows that complete removal, with plastic repair if necessary, gives the most certain and satisfactory result in the type of case for which it is recommended below, and in the majority of cases it has been found that the patients prefer a procedure which will remove the tumour within a specified brief time, instead of a long series of applications which may have to be continued over several months or years. In the hands of some dermatologists radium has been too freely used and too highly extolled.

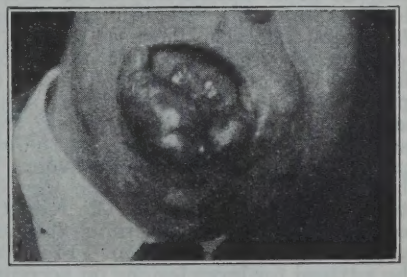
Capillary Type.—In the capillary subdivision fall the small araneus, the flat port-wine stain of all sizes, and the raised, soft, brightly coloured "raspberry" tumour, or "mother's mark," usually about the size of a shilling, and often present at birth.

The "araneus," which resembles a small-bodied spider, can be readily dispelled by touching the central point with a fine electro-cautery, or with the blunt end of an ordinary sewing needle at dull red heat. This may be done without anæsthesia, or a few minims of novocaine may be injected subcutaneously.

The flat capillary tumour of all sizes is best treated by radium, which is applied as a flat plaque. Treatment may take several years, and should always be carried out by an expert, as the dosage must be very carefully estimated, and the margin of error in concentration of the rays is a very fine one. An underdose is ineffectual, and an overdose produces a severe inflammatory reaction followed by scarring and an unsightly and permanent distension of some of the blood-vessels. Some skins appear to be unsuitable for radium application, and show a brownish discoloration below the atrophic skin, from a deposition of hæmatoidin. In such cases excision with plastic repair may be employed. In a suitable case there is a satisfactory blanching of the affected area, and although the skin remains in a permanently atrophied condition, the total improvement may be very considerable.

The small raised tumour, which is chiefly capillary, is best treated by the application of carbon dioxide snow for a period not exceeding 20 seconds. This is the method of election in children, and if properly and smoothly applied leaves practically no scar. On parts other than the face, where several applications of snow would be required, excision is to be preferred. Occasionally there is a considerable cavernous element in the structure of these cases, and carbon dioxide snow is ineffectual; here again excision must be resorted to. The subcutaneous injection of alcohol, while the tumour is emptied of blood by digital pressure, is recommended by some continental authors. It admittedly involves some risk of sloughing, and possesses no advantages over snow application or excision.

FIG. 4.



Massive cavernous condition of tongue, lower lip, and left side of face. Had apparently almost succumbed after electrolysis of tongue in childhood. Suffocation averted by tracheotomy. General health excellent; steady worker in saw-mill. Treatment not desired nor recommended.

Compact Type.—The compact subcutaneous tumour should always be excised. A distension of the superficial capillaries is sometimes found at the most

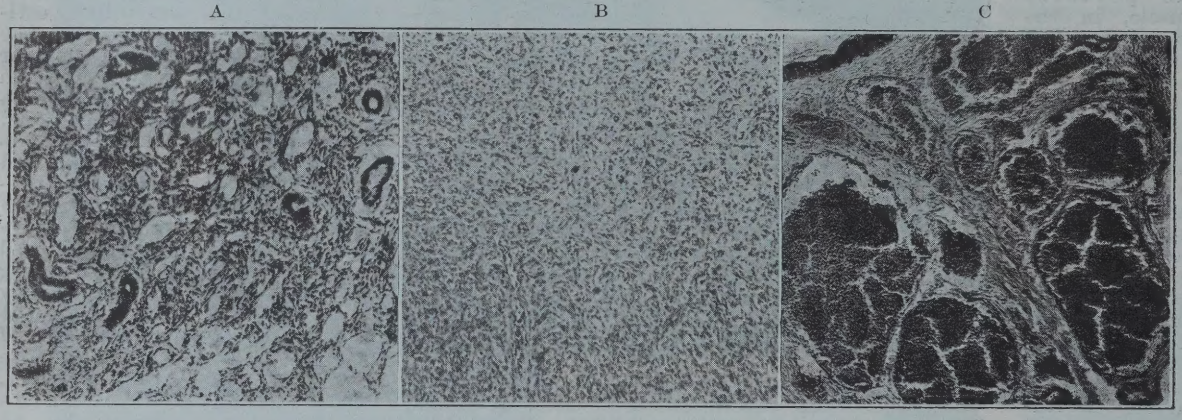
elevated part of the tumour; it is usually possible to include this small area of affected skin with the underlying tumour in the process of excision. The capsule, where it exists, is too thin to permit of any shelling-out process, but the compact mass can easily be dissected from the surrounding connective tissue without troublesome hæmorrhage.

Cavernous Type.—The cavernous tumours present the greatest difficulty in treatment. They are never confined to the skin, and any application of radium which would act upon the endothelium of the deeper blood spaces would involve grave risk to the delicate overlying skin, however careful the screening. The skin should never be sacrificed, even if it overlies an infiltrating subcutaneous tumour. Where primary suture after excision is not possible, the gap may be filled in by local flaps or advancements, but in many facial cases it is necessary to use pedicled flaps, preferably from the forehead.

Summary.

A hæmangioma arises from angioblastic endothelial cells in the vascular layer of the embryo, which remain disjoined, when other similar cell-groups link up to form the blood-vascular system. These small masses proliferate and become vacuolated, giving

FIG. 5.



Sections of A, capillary; B, compact; and C, cavernous hæmangioma.

insertion of radium "needles" into the substance of the tumour is liable to produce a very uneven result in both colour and contour, and may need months of treatment. Electrolysis has been virtually abandoned, partly because of the unevenness and uncertainty of its results, and partly because of the dangerous swelling which may attend its use in ituations in which the method would be of the greatest value, such as the tongue, lips, and buccal mucosa.

In general, excision of the whole substance of the tumour, followed by suture or plastic repair, is by far the most satisfactory form of treatment for the localised swelling, and for the diffuse subcutaneous hæmangioma with localised masses of protuberant endothelial tissue, which is met with chiefly in the limbs. The line of incision must run outside the periphery of the tumour in all aspects, except in situations such as the lip, where the application of small clamps on both sides of the affected area can permit a partial gradual excision. In this removal by stages the fibrosis of the line of repair in the tumour tends to carry on the reduction of size for a considerable time. Cavernous tumours of the tongue present a difficult problem. Free excision is not to be advised for large lesions on account of the mutilation of the organ. Small tumours, however, should be dealt with by wedge exsection. When the whole or half of the tongue is involved, treatment should be withheld, if possible, until after puberty, to allow time for retrogression. The author has recently seen a case of this type in a girl of 11, in which an attack of scarlatina followed by pneumonia appeared to initiate reduction in size. If treatment is imperative at any age, on account of repeated hæmorrhage or gross disorder of speech or mastication, radium needling should be tried, as irregularity of contour is of secondary importance to the reduction in bulk of the tongue. The possible need for tracheotomy should be mentioned beforehand, and the patient should be watched carefully while the needles are in situ and for 48 hours after their withdrawal.

No attempt can be made here to describe the methods of plastic repair for the various regions. Healthy the histological appearance of stunted blind capillaries which contain no blood. This is the capillary type of tumour. Further proliferation of the endothelial cells which form the walls of these fine channels produces the solid compact hæmangioma. The cavernous hæmangioma develops when a connexion is established between the blood-vascular system and the previously closed delicate channels of the capillary tumour. Normal blood then flows through them and ultimately produces marked distension.

The three types are clinically distinguishable, but the structural forms may be intermingled in certain tumours. Usually there is marked predominance of one type.

The treatment of the capillary type is by radium or carbon dioxide snow. The compact and cavernous tumours should be excised.

The untouched photographs (Figs. 1, 2, and 3) which accompany this article have been selected with a view to showing types suitable for excision, and one case (Fig. 4) of very large tumour in which treatment was neither desired nor advised.

BRITISH HOSPITAL FOR CHILDREN, BELGRADE.—This institution is in danger of being closed for lack of financial support. It was opened eight years ago and has been under the control of Dr. Katherine MacPhail, who originally went out to Serbia under Dr. Elsie Inglis during the war. In that period, it is stated by the committee, which is appealing for help, it has "tended, and in many cases rescued from death or from being maimed for life, some 60,000 children whose fathers and mothers were victims of the war." All this was done in spite of the fact that very little help has been forthcoming beyond that generously given by the Serbian Government. At least £3000 a year is needed to maintain the hospital on its present footing.

THE CURATIVE ACTION OF HYDNOCARPATES AND IODIDES IN LEPROSY.

By Sir LEONARD ROGERS, C.I.E., M.D., F.R.C.P. Lond., F.R.S., I.M.S. Ret.; Physician and Lecturer to the London School of Tropical Medicine.

Dr. E. Muir, leprosy research worker in the Calcutta School of Tropical Medicine, has recently published two important papers, one on improvements in the administration of sodium hydnocarpate[1] and the other on the value of iodides and antimony in advanced cases of leprosy[2]; the time, therefore, appears opportune for a brief review of the present position of the treatment. The old Indian remedy, chaulmoogra oil, has long been used orally, but only slightly retards the disease owing to its irritating effect on the stomach. Recently, however, E. A. O. Travers found that fresh *Hydnocarpus anthelmintica* nuts are well borne and have, he thinks, a therapeutic value when given by the mouth. In 1914 Victor G. Heiser[3] reported promising results at Culion, in the Philippines, with intramuscular injections of the Mercado mixture containing chaulmoogra oil, but H. W. Wade and C. B. Lara[4] have recently reported that most of the cases subsequently relapsed, and this "decidedly heroic" method was abandoned. In a series of papers[5 6 7] published between 1916 and 1921 the present writer showed the value of subcutaneous and intravenous injections of the soluble sodium salts of gynocardic and hydnocarpic acids obtained from chaulmoogra oils, preferably that of *Hydnocarpus wightiana*. He also established the important fact that they produced specific reactions with slight fever and local swelling, accompanied by breaking up of vast numbers of the lepra bacilli, and followed by absorption of the thickened tissues and eventual disappearance of the causative organisms. There was apparent cure in no less than 40 per cent. of cases, which were much earlier than the general run of asylum ones. This effective method had the disadvantage of causing blocking of the veins in some cases by a local adhesive phlebitis; this limited its use, especially in women and children, and led to the successful introduction by A. E. Dean and H. Hollmann in Honolulu, in 1918, of intramuscular injections of the ethyl esters in place of the sodium salts and the adoption of this treatment in the Philippines and elsewhere. As recently as 1925, however, G. A. Perkins[8] pointed out that the sodium salts first used by me "in the effective treatment of a large group of cases" are more active than the ethyl esters; their use at the present time is restricted by the gradual obstruction of the veins which they cause.

"*Alepol*," *a New Non-irritating Sodium Hydnocarpate Suitable for Intravenous Use.*

As my own experience leads me to agree with Dr. Perkins that sodium hydnocarpate is a more effective preparation than the ethyl esters, I have been working during the past two years to overcome the disadvantages of the former. At the Royal Society of Medicine in February last[4] I announced that success had been obtained, with the help of Mr. T. A. Henry, D.Sc., Director of the Wellcome Chemical Research Laboratory. After making several preparations he has obtained the sodium salts of selected fractions of the fatty acids of *H. wightiana* oil, which are quite painless when given in a 3 per cent. solution subcutaneously and intramuscularly, and could also be administered in a 1 per cent. solution intravenously with good results. I also enlisted the help of Dr. Muir, who has got over the difficulty of injecting 1 and 2 per cent. solutions intravenously by the simple expedient of drawing up about an equal quantity of blood into the dose, mixing by rotating the syringe on its long axis with the needle in the vein and injecting the whole. The new preparation (which Messrs. Burroughs and Wellcome have put on the market under the name of Alepol) costs one-twentieth of the price per dose of a good ethyl ester, as well as being more active; the powdered drug, ready for making up 2 or 3 per cent. solutions, with 0·5 per cent. carbolic acid, can be supplied at a cost allowing of two full 5 c.cm. doses being given twice a week for a whole year for just over 2*s*. In view of *H. anthelmintica* being less irritating to the stomach than *H. wightiana*, I asked Dr. Muir to make some sodium hydnocarpate from the former for intravenous use, and he has found this preparation to be quite unirritating to the veins. Thus we now have a very cheap, active, painless and specific remedy, which produces reactions in leprous tissues with extensive destruction of the causative bacilli.

At the Royal Society of Medicine discussion Muir,[4] Wade, and Lara (see THE LANCET, 1927, i., 597) recorded over 1000 recoveries, showed that nearly every early case can be "cured" (Muir's own word), and that some 15 to 20 per cent. of advanced cases of eight years' average duration could also be cleared up. I pointed out in that discussion that the power to clear up even the early cases would allow a great reduction of leprosy in a single decade, wherever the simple plan of examining all the household and close contacts of newly discovered lepers every six months for five years could be carried out, as some 80 per cent. of possible new infections would thus be detected and cleared up in the early uninfective stage, and that proportion of foci of infection stamped out. After a second five years' campaign very few would remain. This plan should be feasible among all European and other educated races. What is now wanted is a more effective treatment for advanced cases, and Dr. Muir's second paper on iodides in leprosy promises a further advance in that direction.

History of the Use of Iodides in Leprosy.

Iodides have long been used in leprosy, but nearly all workers agreed that they are harmful on account of the very severe febrile and local reactions they produce, often with the appearance of new lesions. They are, however, of diagnostic value, as they induce the appearance of lepra bacilli in the nasal discharge when these were previously absent. Thus the Norwegian authorities, Danielssen and Boeck, in their classical description of leprosy of 1848, state that the French physician, Biett, was the first to use iodine preparations internally in leprosy, but that they themselves had found that they produced severe reactions followed by only temporary diminution of the nodules. Hansen, in his book on leprosy (1895), states that Danielssen "soon learned what a very dangerous remedy it (potassium iodide) was in this disease," but that he used it as a test of apparent cure, as he considered that if it produced no development of new eruptions the cure was complete. In 1908 E. Marchoux and G. Bourret[9] recorded the interesting observation that during the reactions produced by iodides, both the lepra bacilli discharged from the nose and those in nodules which softened or suppurated as a result of the reactions, showed extensive breaking up and loss of acid-fastness. This is precisely what I found in nodules showing similar reactions after intravenous sodium hydnocarpates, and it led me to persevere with the treatment. The French writers mention that nearly all previous authorities, except Siebart, regarded the iodide reactions as harmful, but they noted improvement and regarded them as specific. Currie, Clegg, and Hollmann,[10] in a valuable review of the literature on leprosy treatment, record that in their hands the inhalation by a leper of 15 to 20 minims of ethyl iodide invariably produced severe reactions within a few hours.

A study of the literature led me to think that the close similarity between the reactions and bacillary destruction produced by iodides and hydnocarpates respectively indicated further trials of the former, in spite of the severity of the reactions they produced. I was strengthened in this belief by noting the greatest

improvement I had ever seen in two advanced cases, in which a very few small doses of sodium hydnocarpate intravenously had produced very severe local reactions, accompanied by debilitating fever of over a month's duration. Yet, without any further injections, the patients continued to improve for a year, and one of them completely lost his extensive lesions and fully recovered his health. In these exceptional cases the toxins set free by the dissolution of immense numbers of lepra bacilli had evidently been followed by the development of curative antigens in the system with ultimate great improvement, or even apparent cure.

I forwarded to Dr. Muir all the abstracts I had made on the treatment of leprosy during two years' study of the literature, and in a letter dated Sept. 29th, 1922, I stated that I would send him "a preliminary account of the history of the methods of treatment, which will bring out the interesting fact that every method, including various vaccines, tuberculin, nastin, iodides, &c., which gave any definite results caused reactions with breaking down of the nodules and of the bacilli." Dr. Muir commenced trials of iodides in 1923, as he informed me in a recent letter, sending early information of the success of his four years' work, which he has just reported.[2] The most important part of this is his discovery that prolonged febrile reactions may be controlled by intravenous injections of tartar emetic, and painful nerve symptoms by subcutaneous injection of adrenalin, for this enables the drug to be given with great advantage, even in many advanced cases of leprosy. Equally important is his conclusion that, when very large doses of potassium iodide can be taken repeatedly without reaction, the case is probably completely cured; this confirms the opinion of Danielssen. Muir rightly warns against the use of this very active treatment by those with little experience of the disease, or anywhere except in institutions with full control and facilities for careful observation; the results in the large series of cases he is now treating with iodides will be awaited with interest.

Thanks to Dr. Muir's kindness in sending me an advance copy of his paper, I have been able to use potassium iodide in patients who had almost cleared up under the new sodium hydnocarpate, and I have found it of undoubted value in producing mild reactions with further improvement in such cases. In two others which I looked on as practically cured no reactions have occurred; this confirms their recovery. I therefore think that the drug may be safely used by experienced workers in cases in which all thickening of the tissues has already cleared up under alepol as the few remaining bacilli will not induce harmful reactions; also as a test of complete recovery. It may thus be used to supplement treatment by alepol and other active chaulmoogra oil preparations, until Dr. Muir's further experience enables him to lay down safe rules for its more general exhibition in active advanced cases, in which iodides may be a two-edged weapon unless used with great care. When we recall that only a decade ago we could do so little for the disease, the present position of the treatment holds out great hopes for the leper.

ROYAL LONDON OPHTHALMIC HOSPITAL.—An extra Gifford Edmonds prize of £100 for the best essay on a subject dealing with ophthalmology involving original work will be awarded in December, 1929. The subject for this essay is Central Scotoma: its Pathology and Clinical Significance. Particulars may be had from the Secretary, Moorfields Eye Hospital, City-road, London, E.C. 1. The subject for the current essay to be sent in by December, 1928, is the Causation and Differential Diagnosis of Proptosis.

A NOTE ON THE USE OF TUBERCULIN IN PULMONARY TUBERCULOSIS,

WITH ESPECIAL REFERENCE TO DREYER'S DIAPLYTE.

BY W. CECIL BOSANQUET, M.D. OXF., F.R.C.P. LOND.,
PHYSICIAN TO THE BROMPTON HOSPITAL, LONDON.

IT can hardly be denied that the introduction of tuberculin by Koch as a specific remedy for tuberculous affections was followed by an enormous balance of disastrous results so far as the subjects of pulmonary tuberculosis were concerned, or that subsequent attempts to revive the use of these preparations as a routine or even a frequent mode of treatment in cases of consumption have been not merely unsuccessful but actively harmful. In consequence the employment of tuberculin in pulmonary tuberculosis appears to have been largely abandoned. It is possible that the pendulum of opinion may have swung too far. Personally, I am inclined to believe that there are a few cases of chronic phthisis in which tuberculin is capable of inducing some degree of benefit. It is clearly desirable not to neglect the smallest aid that is available in a disease against which our weapons of defence are so extremely limited.

Our knowledge of the active principle at work in the various preparations of tuberculin is meagre or entirely lacking. I am inclined to think that the effective body is the same in all forms of tuberculin which have any real activity, the different preparations varying in dilution and in the presence of various extraneous foreign materials, which may complicate the results obtained without increasing the benefit to the patient. I can only speak from experience of Koch's TR and his *bazillenemulsion*, BE, among the old preparations; while recently I have used Dreyer's diaplyte vaccine, which for brevity I will call TD. This paper is written mainly with a view to calling attention to the possible value of this last form of tuberculin.

Since tuberculin is of the nature of a vaccine, we cannot hope to produce good results by its use in patients whose disease is actively progressive, and who are therefore probably suffering already from an overdose of the very poison which we are injecting. Nor is it theoretically likely that such treatment will do good in cases of long-standing and advanced disease, with emaciation and cachexia which have destroyed or gravely impaired the patients' powers of reacting to a toxin by forming increased immunising bodies and so gaining enhanced resistance. As a general principle, therefore, tuberculin should not be administered to patients who exhibit high degrees of pyrexia or who are greatly debilitated. The latter should certainly first undergo a course of hygienic treatment in order to increase their powers of response. A case mentioned below seems to indicate that even pyrexia of high degree is not necessarily an absolute bar to the use of tuberculin, but the vaccine must only be given in such cases with extreme caution. Also it should be an absolute rule of treatment to "let well alone" in early cases. If a patient is doing well on simple rest and hygienic management, or on any other special regimen, we should not, either from impatience or from a light-hearted desire to try some new method, interfere with the process of natural recovery, by the use of tuberculin, artificial pneumothorax, or any other drastic remedy. It is very easy to upset the balance of reparative forces by any kind of shock or disturbance, and it is too often very difficult to regain ground so lost.

The types of case in which I believe that tuberculin may sometimes be of use are: (1) patients who exhibit a persistent mild pyrexia in spite of continued rest in bed; (2) those who have no fever while resting, but suffer repeatedly from a slight return of pyrexia on rising and moving about; and (3) early

cases with slight laryngeal involvement. Prophylactic injections of tuberculin might also perhaps be given advantageously to delicate subjects with bad family histories. I have only had the opportunity of using TD in one such patient, a lad whose mother and sister had recently died with subacute pulmonary tubercle, and whose other sister had recently developed signs of the disease. He has so far (over two years) remained free from symptoms.

Dosage and Technique.

The dose should be almost infinitesimal at first, and should be increased very slowly under careful observation of the temperature chart and of the patient's weight and general condition. A certain psychical effect is often produced by the administration of any new remedy, and the illusory improvement which sometimes appears at first must be discounted. On the other hand, if a patient feels depressed or in any way less well after each injection, I should attach some importance to his sensations and diminish or discontinue the doses. The initial dose which I employ, using Koch's tuberculin, is 1/100,000 mg. of solid bacterial content, followed by 1/75,000, 1/50,000 mg., and so on in a febrile case, raising the doses more quickly in the absence of fever and in early cases. Dreyer's tuberculin is more concentrated, as the inert fatty matter has been removed and the solid material left is theoretically all active substance. I use an initial dose of 1/200,000 mg., and this can be raised slowly or quickly in accordance with the type of patient. In the series of observations mentioned below an initial dose of 1/75,000 mg. was employed in advanced cases and as much as 1/2000 in early disease, without ill-effects; but I have seen instances in which the smaller amount gave rise to marked febrile reaction. When a satisfactory dose has been reached, giving normal temperature and general improvement, it is best to repeat it, at all events for several ensuing injections, as it appears doubtful whether any advantage is gained by raising the dose indefinitely. It has been suggested, probably with truth, that a patient may acquire a tolerance for injected tuberculin even in large amounts and yet not gain increased resistance to the disease from which he is suffering. There seems no reason for aiming at the administration of large quantities of the vaccine.

The first trial injections may be given at intervals of five or seven days. Afterwards the intervals may be determined by the effects produced. Thus, when an injection causes a preliminary fall of temperature, which tends to rise again some days later, the time of such rise may indicate the need for another dose. After an injection an immediate rise of temperature of more than 1° F. usually suggests a diminution of the dose given; in any case it contraindicates any increase. The patient should remain in bed, and so far as is possible at complete rest, during the first two or three months of the treatment, so that no avoidable disturbance may vitiate the strict observation and record of the results obtained.

A Series of Cases.

The series of observations on the use of TD on which this note is based was carried out by my colleague, the late Dr. A. C. Inman, on some of my patients at Brompton Hospital, at the request, I believe, of the Medical Research Council, my own part in the matter being confined to general clinical supervision and advice. We submitted, rather more than two years ago, a joint report to the Council, with details of individual patients, temperature charts, and post-mortem notes in fatal cases. This was apparently not considered to be of sufficient interest for publication. Owing to the recent death of Dr. Inman, which has deprived me of the hope of further collaboration with him in such research, I have felt that his painstaking investigations into the value of TD, carried out as they were with all the exactitude of a trained scientific worker, deserved a better fate than to repose in the pigeon-hole of a Government Department. Although no definite conclusions could be drawn from the few cases available, he obtained, at any rate, some indications which might be of interest to other investigators and lead to further trial of this form of tuberculin. For the sake of brevity I shall note only a few points which struck me at the time.

At the beginning of the trial Inman chose for his subjects cases of advanced disease, many of them clinically apparently hopeless. This was done, I understood, by desire of Prof. Dreyer, who preferred that his preparation should obtain no fictitious credit from being used on patients who might be expected to improve in any case. Such a choice of cases would naturally be unfavourable to any statistical examination of the results obtained; nevertheless, it proved fortunate otherwise, since it was from a study of the fatal cases that the most definite indications as to the action of TD were obtained. Carefully administered, the tuberculin produced, so far as could be judged, no ill-effects even in these unfavourable subjects. Indeed, several patients appeared to put up an unusually good fight against the disease. One girl, aged 17, who was sent into the hospital as hopeless and unlikely to live many months, went out restored to some degree of activity and has only recently died—four years after her first admission. An older girl of 21, equally ill, lived for 11 months and seemed at first to make some improvement; while a third, who exhibited throughout a remittent or intermittent pyrexia reaching almost invariably 101°–103° F. in the evenings, also lived for 11 months—a long duration for a patient suffering apparently from so active an infection. In these cases of long duration which came to necropsy Inman noted an almost complete absence of caseation throughout the body and an unusual development of fibrous tissue around the lesions; and in the last-mentioned case there was found throughout the chest and abdomen an immense number of small, firm, white lymphatic glands, somewhat resembling haricot beans and showing no trace of caseation or softening. Clinically, it would be easy to parallel any one of these cases with others treated by ordinary methods; but it seemed to us a larger number, among our eight very advanced cases, than might have been expected on the theory of chances. The post-mortem findings suggested that some increase or at least modification of the process of resistance had occurred—in one instance apparently connected with the lymphatic system—which would correspond with the slow downward course as observed clinically in these patients.

Of the moderately advanced cases a considerable proportion improved satisfactorily at the time. The final results are not very encouraging—of 21 cases, two are well and at work, nine are alive but not able to work, nine have died, and one is unaccounted for; but, as stated above, little benefit could be expected from the use of tuberculin in this type of case. Of early cases (eight) all are alive and at work, the average interval since the end of their treatment being about three years. Two cases of tuberculous glands, and one of tuberculous peritonitis did well, and in cases complicated by laryngeal affection this condition usually seemed to be favourably influenced.

Diaplyte Vaccine in 1927.

I have myself used diaplyte vaccine in nine cases during the past year. Of these, six were cases in which there was persistent pyrexia in spite of rest in bed, and in four of these a permanent fall of temperature to normal limits was effected. In the fifth case, after a preliminary fall of fever, a relapse occurred and no permanent benefit resulted; while in the sixth, an advanced case in which the vaccine was only tried as a last resort, no good was produced beyond the psychological effect of the new remedy. The other three patients suffered from laryngeal tuberculosis with comparatively slight involvement of the lungs. In two marked improvement took place; in the third only slight immediate benefit, the patient going to a sanatorium for further treatment. Here, again, the numbers are too small to admit any inference to be drawn, but I am sufficiently encouraged to make further trial of the preparation.

In conclusion, I would mention two questions which have occurred to my mind in connexion with these investigations: 1. Is it right on completion of a course of tuberculin treatment to discontinue the injections suddenly, or should one withdraw the remedy gradually lest the patient should miss an accustomed stimulus? In Inman's cases sudden cessation was the rule, and I have hitherto followed

this procedure; but a more gradual withdrawal would seem theoretically desirable. 2. It not infrequently happens during a course of tuberculin injections, which is producing apparent benefit to the general condition and to the disease in the lungs, that a sudden attack of pleurisy intervenes and apparently undoes all the good work. The explanation is not clear. Can it be that tuberculin increases the local resistance, in the form of fibrosis,[1] and has little or no effect on the general (humoral?) immunity of the patient, in whatever this may consist?

I take this opportunity of expressing my sincere thanks to Prof. Dreyer for his kindness in furnishing me with a liberal supply of his vaccine.

THE SCHICK TEST AND IMMUNITY TO DIPHTHERIA.

BY ROBERT CRUICKSHANK, M.D. ABERD., D.P.H.,

RESIDENT ASSISTANT MEDICAL OFFICER, BELVIDERE HOSPITAL FOR INFECTIOUS DISEASES, GLASGOW.

ALL probationer nurses on the staff of Belvidere Hospital for Infectious Diseases, Glasgow, have been, since 1922, tested by the Schick test for susceptibility to diphtheria. They are tested from two to four months after commencing nursing duties, as they are on probation for three months before being permanently appointed to the staff. During 1926, 85 probationer nurses, whose ages ranged from 18 to 24 years, were Schick tested, and of these 25 (or 29·4 per cent.) reacted positively. Groups of about 20 nurses were tested at one time, and in each batch the number of positive reactors was about 30 per cent. Twenty-four of the twenty-five nurses who reacted positively were given immunising doses of the prophylactic toxoid-antitoxin mixture (Burroughs Wellcome and Co.). A small initial dose of 0·1 c.cm., as a test of sensitivity, was first injected subcutaneously, followed three days later by a 1·0 c.cm. dose, and at weekly intervals thereafter by second and third doses of 1·0 c.cm. One nurse gave a moderately severe reaction after the first 1·0 c.cm. dose (temperature 101° F., arm painful and swollen, sore-throat, and general malaise), and seven nurses had slight elevation of temperature, with painful arm and some malaise. The others, apart from some stiffness of the arm, did not complain.

Ten out of 12 nurses immunised in April, 1926, were retested in November, and two of these still gave weak positive reactions. These two nurses were given a further dose of 1·0 c.cm. of the toxoid-antitoxin mixture in December, 1926, and when retested in March, 1927, reacted negatively; 11 of the 12 nurses immunised in December, 1926, were retested in March, 1927 (three months after immunisation). All reacted negatively, and when tested a fortnight later with a stronger dilution of toxin only one gave a weak positive reaction. Individuals who prove refractory to the ordinary course—probably because of a deficient antibody reaction in their "make-up"—require a more intensive course of immunisation, and it is obviously important that immunisation should not be discontinued until the patient has become negative to the Schick test. Such people are analogous to the patients, of whom there are well-authenticated instances, who develop second and third attacks of diphtheria.

Value of the Schick Test.

From January, 1924, to January, 1927, six out of a total of some 200 probationer nurses who joined the staff during that period developed faucial diphtheria *before they were Schick-tested.* Of those who were Schick-tested, two nurses developed sore-throats and had positive cultures, but did not show any evidence of clinical diphtheria; one of these had been Schick-positive, and had been given the full immunising course two years previously, while the other had been Schick-negative. One nurse who had given a strong positive reaction developed faucial diphtheria with extensive membrane on both tonsils and uvula six weeks after immunisation, and before a second Schick test was done. Altogether, therefore, during the past three years only one nurse has developed clinical diphtheria after being Schick-tested; in her case the disease appeared six weeks after immunisation, a period regarded as being too early for the complete development of immunity.

During the years 1916–21—that is, in the period prior to immunisation—there were 30 cases of clinical diphtheria among the nursing staff of the hospital, or an average of five every year, which, in addition to the impairment of health of the individual and the crippling of the staff, was costing the corporation approximately £90 per annum. The cost of immunisation has been reckoned by Graham Forbes[1] as about 3*s.* for every school-child; it must be considerably less for a hospital nursing staff. The cost of immunising a fresh batch of 50 probationer nurses each year would, therefore, not exceed £5.

These results illustrate the value of modern methods in controlling the incidence of diphtheria among the personnel of a fever hospital. All nurses should be Schick-tested immediately on joining the hospital staff, and only those reacting negatively should be allowed to nurse in diphtheria wards until such time as the positive reactors have been immunised.

Environment.

It has been shown by W. H. Park,[2] J. L. Lavan and E. C. Black,[3] and others, that town dwellers develop an immunity to diphtheria more quickly and in greater proportion than do country dwellers, and, further, that a larger percentage of slum-bred children are Schick-negative than are the children of the well-to-do classes. An analysis of the previous environment of 50 nurses who reacted positively to the Schick test showed that 20 had lived in the country or in villages, 18 in small towns or in the suburbs of large towns, and 12 in large towns—i.e., 38 (or 76 per cent.) had been brought up in the country or in small towns. A similar analysis of 50 nurses reacting negatively showed that 34 (or 68 per cent.) had lived in the country or in small towns. In other words, practically the same proportion of those who had developed immunity to diphtheria came from the country, as did those who were susceptible. It is therefore suggested that age eliminates the influence of environment in the development of a gradually acquired immunity.

Summary.

The testing of nurses by the Schick method, and the active immunisation of those found to be susceptible to diphtheria has given satisfactory results, and has almost entirely eliminated the incidence of clinical diphtheria among the nursing staff of a large fever hospital.

I wish to thank Dr. T. Archibald, medical superintendent of Belvidere Fever Hospital, Glasgow, for permission to publish this work, and Dr. R. A. O'Brien, of the Wellcome Physiological Research Laboratories, for the material and many helpful suggestions.

[1] The different possible actions of tuberculin were discussed by Dr. Georg Schröder in his article on Specific Stimulation Therapy and Protective Inoculation in Tuberculosis, THE LANCET, 1927, i., 167.

EXTENSION OF BRADFORD MUNICIPAL HOSPITAL.—Proposals are being considered for the extension of the operating facilities and the provision of additional accommodation for nurses. In 1920 there were 428 operations; last year the number reached 2249. The present nurses' home holds only 50 of the 200 nurses; the remainder are housed in old buildings which are said to be fit only for demolition.

THE MORTALITY OF OPERATIONS UPON THE ENLARGED PROSTATE.

BY HAROLD EDWARDS, M.B. LOND., F.R.C.S. ENG.,
SURGICAL TUTOR AND TEACHER IN CLINICAL SURGERY, KING'S COLLEGE HOSPITAL.

RECENTLY published statistics showing the deaths after operation upon the enlarged prostate in this country compare very unfavourably with the low mortality-rate claimed by surgeons in America and on the continent. The mortality of four London hospitals is said to vary between 13·1 per cent. and 20·1 per cent. for enucleation of the prostate, and between 12·9 per cent. and 20·8 per cent. for all operations, including suprapubic cystotomy and enucleation of the prostate by the single-stage and the two-stage methods.[1] It is doubtful whether any operative procedure upon a non-malignant condition is justifiable if the death-rate be 20 per cent. or over. The prognosis for the patient with prostatic disease appears even gloomier from the comparisons made by Sir Cuthbert Wallace, in his recent Bradshaw lecture[1] at the Royal College of Surgeons, between the mortality-rates of operations upon hospital patients in the two periods 1910–16 and 1922–26. Though these figures show the mortality in suprapubic enucleation to have decreased from 20·2 per cent. to 14·5 per cent., the total operative mortality (including cystotomy alone) had actually risen from 20·2 per cent. to 22·5 per cent. The figures indicate either a lack of progress in operative technique or a failure on the part of the practitioner to recognise the condition before the renal function is impaired—for, apparently, uræmia is the most frequent cause of death, and hæmorrhage a rare complication of the operation.

The high mortality figure led me to investigate the post-operative mortality for operation upon the enlarged prostate at the Urological Clinic in King's College Hospital. The five years 1922–26 were taken, and the following figures obtained :—

1222–26.—Total operation cases, 136. In 126 cases the prostate was removed; in 122 cases this was performed in one stage, with ten deaths, giving a mortality of 8·2 per cent. In four cases the operation was done in two stages, with one death, bringing the total mortality of prostatectomy to 8·7 per cent.

Prostatectomy.	No. of cases.	Deaths.	Percentage mortality.
1. Single-stage operation ..	122	10	8·2
2. Two-stage operation ..	4	1	25·0
Total	126	11	8·7

In ten cases suprapubic cystotomy alone was performed with seven deaths, making the total mortality for all three operations 13·2 per cent.

These figures, though not unduly low, are more encouraging.

Technique.

I wish to lay particular emphasis on the operative technique employed in these cases as a routine, which is that introduced by Sir John Thomson-Walker, and usually described as "open prostatectomy." This is an unfortunate misnomer, and appears to have led to a misunderstanding of the method. Sir Cuthbert Wallace, in his Bradshaw lecture,[1] suggests that the prostate is removed under the eye of the surgeon. This, however, is not so. In the Thomson-Walker operation the enucleation of the prostate is done blindly, and the prostate is not seen until it is withdrawn from the suprapubic wound. This is the first stage of the operation. As soon as removal has been effected, the patient is placed in the Trendelenburg position, and the prostatic cavity is exposed by placing a self-retaining retractor in the bladder. The necessity for this step is frequently obvious. Large tags of torn prostatic capsule are often seen bridging across the internal meatus, particularly in cases in which the prostate was of the "adherent" type. Small residual adenomata are sometimes seen. Removal of such tags and nodules is readily effected by means of long curved scissors. Often one or two vessels can be seen throwing a stream of blood across the cavity from side to side; these can be caught in artery forceps and ligatured. Finally, a continuous hæmostatic suture is inserted between the posterior lip of the meatus and the adjacent edge of the prostatic capsule, and there is usually no further bleeding at all. With a perfected technique the whole operation, from the time of the incision in the skin to the insertion of the last stitch, should not take longer than 20 minutes.

The operation has suffered much adverse and totally undeserved criticism. This may be partly due to misunderstanding created in the minds of critics by the unfortunate description of the operation as an "open prostatectomy," but the attitude of most critics rouses a suspicion that they have not read the description completely, and have never actually seen the operation performed. In surgical text-books, with one or two notable exceptions, the operation is mentioned only to be condemned. First, because the exposure of the prostatic cavity is alleged to prolong the operation unduly and unnecessarily. As has been stated, the operation should be completed within 20 minutes, so that any criticism on this basis is unwarranted. Secondly, because "shock" is stated to follow the insertion of the bladder retractor and examination of the prostatic bed after enucleation. The most recently published British text-book on surgery, in advocating irrigation of the prostate cavity immediately after operation to secure hæmotasis, states :—

"This practice (irrigation) will obviate the necessity for pulling up and exposing the prostatic bed to arrest hæmorrhage, as advocated by Thomson-Walker, a proceeding attended by *great shock.*"

The prostatic bed is not "pulled up" in the Thomson-Walker operation. Hæmostasis is obtained by ligature of obvious bleeding points, and by the introduction of a hæmostatic suture. This procedure cannot be responsible for any appreciable amount of shock. If it were, shock should figure largely in this series as a cause of death after operation. (The causes of death in the fatal cases are given below.) Further, the total mortality of the operation could not be expected to compare as favourably with that given for the blind operation of Freyer if the amount of shock were appreciably greater. No one can dispute that a varying degree of shock is always associated with prostatectomy, however performed. The shock is due almost entirely to the enucleation of the prostate from its bed. Criticism of the Thomson-Walker operation on these lines is therefore groundless.

Indirect criticism is levelled at the operation, in other books, by upholding the older method of Freyer, which is stated to be highly satisfactory, and the cases to do "quite well." "Quite well" is a broad phrase. It may justly be applicable to the immediate prognosis of Freyer's operation but, judging from the series of cases which have attended the Urological Clinic for difficulty in micturition after having a prostatectomy done by the Freyer method some years previously, and by the 69 cases of severe obstruction following prostatectomy by the Freyer method recently published,[2] it must be modified. Such cases are usually shown at operation to have a dense mass of tissue filling the prostatic cavity, with a pin-hole internal meatus. It is true that one case attended the clinic with obstructive symptoms five years after prostatectomy by the Thomson-Walker method, but this was due to the growth of a fresh adenoma from prostatic remains. The specimen was shown recently at a meeting of the Urological Section of the Royal Society of Medicine. It was successfully removed at the second operation, and the case is included in the present series.

[1] Cuthbert Wallace: THE LANCET, 1927, ii., 1059.

[2] Thomson-Walker: THE LANCET, 1927, i., 1009.

The criticisms of the operation, therefore, are groundless. The operation, in fact, is abundantly justified by the mortality from it, which compares very favourably with that of any recent figures published for the older operation, and by the fact that the risk of subsequent obstruction is reduced to a minimum.

Causes of Death after Operation.

Of the 11 deaths following removal of the prostate, ten followed the single-stage operation, giving a mortality for that operation of 8·2 per cent., and one followed the two-stage operation, a mortality of 25 per cent. (for four cases) for that method. The total mortality for both methods was 8·7 per cent. The ages of the patients who died ranged from 63 years to 79 years, ten being 65 and over. The mean for the group was 69·4 years. This is above the average age for all cases operated upon (65·5 years). It is of great interest to note that of 28 patients operated upon under 60 years, not one was lost.

Of the ten deaths following the single-stage operation the following causes are recorded: uræmia, 4; pyelonephritis, 2; cardiac failure, 2; hæmorrhage, 1; shock, 1. After the two-stage operation one patient died from acute broncho-pneumonia.

In order to dispel any doubts with regard to the assignment of these causes, a short note is given on each case.

Uræmia.

CASE 1, aged 67.—Death occurred nine days after operation. On the day preceding death the blood-urea was 250 mg. per c.cm. Before operation there were no symptoms of renal insufficiency, and the urea concentration in the urine was over 2 per cent.

CASE 2, aged 75.—Death occurred in 48 hours. The blood-urea before operation was 52 mg. per c.cm. The patient recovered for a short while after the operation. In the first 24 hours the urine was coloured red, but there was no severe hæmorrhage.

CASE 3, aged 63.—Death occurred 19 days after operation. For a few days preceding the death hiccough was incessant, and during the last two days there was vomiting. Before operation the blood-urea was 93 mg. per c.cm. There were no symptoms of uræmia, and the urea concentration in the urine averaged 1·93 per cent.

CASE 4, aged 67.—Died on the seventh day. Commenced to hiccough on the third day and did not cease until the collapse, which preceded death. There was severe and intractable constipation.

Pyelonephritis.

CASE 5, aged 65.—Death occurred on the fortieth day after operation. Post-mortem examination showed acute pyelonephritis and ureteritis. The renal pelvis and calyces were dilated. The pelvic colon was also inflamed, and ulcerated.

CASE 6, aged 79.—Death occurred on the seventeenth day after operation. Post-mortem examination showed acute suppurative pyelonephritis, with dilated pelves and calyces This patient was a diabetic, and on admission the blood-sugar was 0·31 per cent. After appropriate treatment of the diabetes the blood-sugar was reduced to 0·121 per cent. by the day of operation.

Cardiac Failure.

CASE 7, aged 65.—Death occurred on the eleventh day after operation. Well in the morning, he suddenly collapsed and died. Death was no doubt accelerated by the troublesomeness of the patient, who, on the second day, contrived to remove both drainage-tubes and catheter, and walk about out of bed.

CASE 8, aged 73.—Died 18 hours after operation. Was emphysematous and had an enlarged heart. He was pronounced fit for operation by the physician. Before death the heart was dilated, with coupling of the beats.

Hæmorrhage.

CASE 9, aged 65.—Death occurred from hæmorrhage 24 hours after operation. The cavity was packed twice without avail.

Shock.

CASE 10, aged 77.—Died within 12 hours of operation, without regaining consciousness. Bleeding from the prostate cavity was practically nil.

Acute Broncho-pneumonia.

CASE 11, aged 67.—Died 34 days after operation. Post-mortem examination showed acute broncho-pneumonia.

Commentary.

The most biased critic of the Thomson-Walker operation will admit that one death from hæmorrhage out of 126 cases (less than 0·8 per cent.) is a low figure—perhaps lower than can be shown for a similar series of operations by the old method of Freyer. The value of examining the prostatic cavity for bleeding points, and of the hæmostatic suture, is self-evident. The low mortality from operative shock (again less than 0·8 per cent.) affords ample proof that the second part of the operation makes no appreciable addition to the shock due directly to enucleation. In both cases of death due to pyelonephritis, the renal calyces and pelves were dilated. It is probable, too, that in three of the four cases in which uræmia was the cause of death, sepsis played a part. Patients rarely die from ascending pyelonephritis if the kidneys are healthy. Sepsis and uræmia together account for 60 per cent. of the deaths following the one-stage operation, and are therefore the complications most to be feared. This relatively high mortality can only be eliminated by earlier operation. It is not so much a question of better diagnosis, which is not as a rule difficult; it is realisation of the dangers of delay in sending a case to hospital that alone can reduce the mortality. Many of the cases operated upon attended hospital for the first time with acute retention, and usually there was a history of increasing difficulty for many years. The practice of "cooking" a prostate until it is bad enough for operation cannot be too strongly condemned, and until it is abolished sepsis and uræmia will always be the predominant causes in any operative mortality list.

Cardiac failure is in rather a difficult category. In any major operation, in which shock is unavoidable, on men over 60 years of age, occasional deaths from this cause must occur, and careful selection of cases is necessary if it is to be avoided.

Clinical and Laboratory Notes.

A CASE OF CEREBELLAR TUMOUR.

BY A. GURNEY YATES, M.D. EDIN., M.R.C.P. LOND.,
PHYSICIAN, SHEFFIELD ROYAL INFIRMARY.

THIS case is similar in several respects to that of intracranial neoplasm described by Dr. John Inkster in THE LANCET.[1]

The patient was a female child of 5, with a history of a purulent discharge from the right ear since she was 8 months old. For several weeks she had suffered from bilious attacks, which, however, were infrequent and attracted little attention. Three weeks before attending hospital on Oct. 24th vomiting began to occur almost daily, and other symptoms suggestive of intracranial disease made their appearance. A squint developed, she began to complain of headaches, her walking was noticed to be unsteady, and her mentality became increasingly sluggish. The pupil reactions were normal, but the right pupil was a little larger than the left, and the right optic disc showed very slight swelling, the left being normal. There was an internal squint from paralysis of the right sixth nerve. There was no nystagmus, the tongue was clean, and the temperature and respirations were normal. The right ear was discharging, but there was no tenderness over the mastoid process. The child looked ill, and mentally was slow and dull. Both arms were ataxic, the right being definitely more so than the left. The muscles of the right arm were atonic, and the biceps and triceps jerks were absent on both sides. Both legs were slightly ataxic and the knee- and ankle-jerks were absent. The plantar reflexes were flexor.

The history and symptoms were strongly suggestive of a right cerebellar lesion, and in view of the old infection in the right ear she was sent to the wards with a provisional diagnosis of a right-sided cerebellar abscess.

The mastoid and the middle and posterior fossæ of the skull were explored by Mr. W. S. Kerr but no pus was found. Her condition remained unchanged for several

[1] THE LANCET, 1927, ii., 1074.

days and a further exploration of the right cerebellar region was contemplated, but she suddenly died.

At the autopsy the cerebral convolutions were found to be flattened and the ventricles greatly distended. A very well-defined pressure cone was seen on the inferior aspect of the cerebellum, distorting the medulla. There was no meningitis, but on opening the right lobe of the cerebellum a tumour, somewhat larger than a large walnut, was found embedded in its substance. It was firm in consistency and translucent in appearance. On section it proved to be a glioma.

As in Dr. Inkster's case, the presence of a primary focus of sepsis and the comparatively recent onset—though in my own case slight symptoms had been present for several weeks—led to the erroneous diagnosis of an abscess. The almost complete absence of optic neuritis supported this error, as severe and early optic neuritis is the rule in cerebellar tumour.

A CASE RESEMBLING ADDISON'S DISEASE

TREATED WITH PITUITARY EXTRACT.

By EDWARD C. B. IBOTSON, M.D. LOND.,
MEDICAL OFFICER, DOLGELLY UNION AND LONDONDERRY HOSPITAL, MACHYNLLETH.

THE following case is of interest because: (1) Addison's disease is uncommon; (2) a case of such deep pigmentation is not often seen; (3) the apparent reaction to pituitary extract is unusual; (4) mental symptoms and headache were marked; (5) benefit was apparently derived from pepsin and pancreatin (pancreas is supposed to be antagonistic to suprarenal).

I first saw the patient, a widow, on Sunday, Jan. 2nd, 1927, when I was told that she had been ill for three years, off and on. I found her very asthenic; the pulse was slow, very feeble, soft, and compressible; voice very weak; temperature 97° F. She complained of severe headache; she had some bronchitis, but no signs of pulmonary tuberculosis, and the sputum was negative. She was vomiting up food, froth, and mucus. She was deeply pigmented everywhere, her face a chocolate colour, hands nearly black, chest, back, and abdomen all a deep chocolate; black pigment inside mouth on gums, cheeks, and tongue. I was informed that she was noisily delirious at night. I concluded that she had Addison's disease. There was no anæmia or wasting and the urine was normal throughout.

I put her on whole pituitary gland, grs. 2, night and morning, with the idea of raising the blood pressure. Moreover, Sajous considers that the pituitary stimulates adrenal secretion. I also gave her tablets of pepsin and pancreatin, grs. 2½ of each t.d., and ordered her invalid Bovril, Bengers Food, and soda and milk.

I intended to give suprarenal gland when I obtained a stock, but I did not give it as the improvement from the first was rapid and extraordinary. By Jan. 5th the mental state had become normal and the vomiting had quite ceased on Jan. 8th. The systolic blood pressure on Jan. 14th was 115. She was retaining all food and growing cheerful. I saw her again on the 25th, when she was up and dressed and apparently quite normal in every way, cheerful, and active, and her eyes bright. The pigmentation had not altered at all. On Feb. 25th she had had a return of the asthenia, which was again cured by whole pituitary in doses of 2 g. (Burroughs Wellcome tabloids) night and morning. Her systolic blood pressure in May was 122.

The patient remained under observation until September, 1927, and gained sufficient strength to come and see me at the surgery, a distance of over a mile. An attempt to substitute adrenal extract for pituitary met with no success, nor did another make of pituitary give the same feeling of well-being. The blood pressure kept up to 120 systolic. The eyes were remarkably bright, in fact lustrous. The pigmentation remained quite unaltered. The mental state was peculiar, she had suspicions that people were watching and following her and trying to rob her. She left the district in September, travelling alone, but I hear that she is still alive and keeping up and about.

The case does not present any aspect of pernicious anæmia; the hæmoglobin and red cell counts were nearly normal. None of the many forms of pigmentation mentioned by Osler fits in with the facts of this case. The asthenia was profound and the vomiting severe, and together with the long duration and the deep pigmentation seem to indicate some form of suprarenal disease. Apparently there is much more disturbance of the suprarenal cortex in this patient than of the medulla. Osler mentions cases of Addison's disease living from six to ten years, and even cases of recovery. This case appears to favour Sajous's view that pituitary extract stimulates the production of adrenalin.

A CASE PRESENTING A CLINICAL PICTURE OF CONGENITAL HEART DISEASE

WITH CONTRARY PATHOLOGICAL FINDINGS.

By NOEL F. PEARSON, M.R.C.S.ENG.,
HOUSE SURGEON, BRADFORD CHILDREN'S HOSPITAL.

THE interesting feature of this case is the almost typical picture of congenital heart malformation, associated with very unexpected and unusual post-mortem findings.

The patient, a boy aged 6 weeks, was the fourteenth child. He was brought to the Bradford Children's Hospital because he had not thrived since birth. The mother said he had been a seven-months' baby, but the birth-weight was 7 lb. 1 oz. Since birth there had always been feeding difficulties, and the child had always had a blue tinge about its face and lips.

Clinical Examination.—Weight 6 lb. 6 oz. The marked feature was the colour of the child; its face and lips had a bluish-green appearance, and its extremities were bluish-pink and cold. The heart showed no enlargement, but a fairly loud double murmur was audible over the whole of its precordium, more marked at the base.

Clinical Course.—During the time the child was in hospital it took its food fairly well, but lost 3 oz. in weight. Some days the cyanosis was more marked than others. On five occasions it had a slight rise in morning temperature (to 99·6° F.). Diagnosis: congenital heart disease. The child died three weeks after admission.

Post-mortem examination included all the organs except the brain. Nothing abnormal was found beyond a certain amount of free fluid in the abdominal cavity, until the heart was examined. There was no excess of free fluid in the pericardial sac. On the anterior surface of the right ventricle was a patch of pericarditis, about the size of a two-shilling piece. The heart was slightly enlarged generally, but the chambers, all the valves, the aorta, and the pulmonary artery were perfectly normal.

The only conclusion is that death was caused by some general infection, unknown, of which the pericarditis was a local manifestation.

My thanks are due to Dr. W. Hayburn, hon. physician, and Dr. Ralph Rimmer, pathologist to the Bradford Children's Hospital, for permission to publish this case.

TREATMENT OF DIPHTHERIA CARRIERS.

By PAUL BOUSFIELD, M.R.C.S. ENG.,
PHYSICIAN TO THE LONDON NEUROLOGICAL CLINIC, MINISTRY OF PENSIONS.

THE waste of time and money sometimes involved in the treatment of diphtheria carriers is well known to all medical officers of health, and any method of treatment which gives promise of certainty in its action is worth pursuing further. I therefore feel that a note on a method recently practised by myself may be of some interest.

I recently had a carrier who for three months defied the usual method of painting with Löffler's solution. An occasional single negative swab was obtained from the throat, but never a sequence of them. I then had the throat *sprayed* with an atomiser and afterwards painted with a 5 per cent. solution of mercurochrome 220. This was done daily for a week and at the end of that period three consecutive negative swabs were obtained. I have since used the same treatment on another carrier with a similar result; in a week the throat was quite free from the Klebs-Löffler bacillus.

While the number of cases does not prove mercurochrome 220 to be a specific, yet it is sufficiently suggestive to make it worth the serious consideration of practitioners. Mercurochrome 220 is not nearly so unpleasant in the mouth as Löffler solution, and this is by no means unimportant when dealing with children.

Medical Societies.

PATHOLOGICAL SOCIETY OF GREAT BRITAIN AND IRELAND.

A MEETING of this Society was held in the Medical School, St. Thomas's Hospital, London, on Jan. 6th and 7th, Profs. L. S. DUDGEON and J. M. BEATTIE in the chair.

G. SCOTT WILLIAMSON and INNES H. PEARSE (London) hold that Graves's disease is due to an excess of the real secretion of the thyroid gland which contains no iodine and does not accelerate the metamorphosis of tadpoles. A short course of iodine, partial excision or rest in bed all lead to the appearance of colloid which contains iodine and is active in the tadpole test.—J. DAVIDSON (Glasgow) described an example of the rare condition in which osteophytes arise inside the skull during the puerperium; the dura is thickened and œdematous and contains foci of amorphous calcareous deposit as well as true bone.—S. C. DYKE (Wolverhampton) detailed a case of long-standing jaundice with multiple xanthomata and splenomegaly, the latter due to great numbers of large phagocytic cells showing no lipoid histologically, though on chemical analysis the spleen contained much cholesterol: the blood cholesterol was extremely high.—J. B. DUGUID and J. MILLS (Cardiff) had found that doubly refractile crystals developed in tissues kept in watery liquids even after thorough fixation in formalin.—G. HADFIELD (Bristol) had met with four cases of acute bilateral necrosis of the globus pallidus, three of them after coal-gas poisoning. There was extensive ferruginous infiltration of the walls of the blood-vessels which was found also in many normal brains.—M. J. STEWART and S. J. HARTFALL (Leeds) drew attention to the abundance of lipoidal foamy cells in the stromata of certain tumours, due to the phagocytosis of the remains of degenerated tumour cells. They also described a case in which multiple adenomata composed of pancreatic islet tissue were found in the pylorus and duodenum.—T. LUMSDEN (London) discussed the causes of regression in implanted tumours; this, he thought, was due in immunised animals to the tumour cells being killed by blood antibodies and the secretions of leucocytes rather than to a failure of the host to provide stroma.—A. M. BEGG and J. A. MURRAY (London) from a study of the growth of a filtrable fowl tumour concluded that the tumours resulting from the inoculation of dead cells arose from the endothelium of the blood-vessels of the host; hence the tumour was a real endothelioma—J. S. YOUNG (Leeds) by putting a mixture of Soudan III bile-salts and oil into the pleural cavity had induced remarkable proliferation, hyperplasia, and metaplasia of the pleural endothelium and the alveolar epithelium, in one instance going as far as stratified squamous epithelium.—L. J. WITTS (Cambridge) described the increase in the monocytes of the blood which could be induced by *B. monocytogenes* and extracts of lymphoid tissue.—R. MUIR and J. S. YOUNG (Glasgow) found that free hæmoglobin circulating in the blood was not excreted into the bile; it did not lead to an accumulation of iron in the liver but in the kidney.—A. E. BOYCOTT (London) discussed the use and abuse of the word "antigen."—A. FELIX and L. OLITSKI (Jerusalem) described a long series of observations on the use of preserved bacterial emulsions for diagnostic agglutination tests by qualitative receptor analysis; H agglutinins are often absent in human typhoid and nothing is so satisfactory as live bacilli.—F. W. ANDREWES (London) had noticed that the colonies of hæmolytic streptococci on plates could be distinguished into "rough" and "smooth"; the rough were more virulent and agglutinated specifically, the smooth giving group reactions.—G. H. EAGLES (London) dealt with the same topic; he had found rough, smooth, and intermediate colonies by continued culture on serum agar; in one case the rough, in another the smooth were more virulent. The forms were quite distinct by agglutination but yielded equal amounts of the same toxin.—F. S. FOWWEATHER (Leeds) preferred the neutral potassium oxalate method with neutral potassium gold chloride for the preparation of gold sols for the Lange test.—A. T. GLENNY, C. G. POPE, and H. WADDINGTON (Beckenham) found a borax-boracic acid salt mixture the best diluent for Schick toxin.—R. A. O'BRIEN and C. C. OKELL (Beckenham) said that human experience had shown that diluted toxins for the Schick and Dick tests kept quite satisfactorily in this diluent.—G. R. JAMES, A. JOE, and R. SWYER (London) found that scarlet fever toxin could be preserved without loss of potency for Dick testing by drying over sulphuric acid and phosphorus pentoxide.—T. DALLING (Beckenham) reported that *welchii* toxin and antitoxin could be titrated by intravenous injection in mice, intradermically in guinea-pigs, or by the hæmolytic effect in vitro, and proposed a provisional antitoxic unit.—P. HARTLEY (London) found that the simultaneous injection of muscle extract or peptone broth much depressed the antitoxic response of a guinea-pig to a second injection of diphtheria toxin.—C. H. BROWNING and R. GULBRAUSEN (Glasgow) showed that experimental trypanosomiasis in mice might be ultimately cured after repeated relapses by giving the same dose of the same trypanocidal preparation.—W. H. TYLER (Cardiff) described the preparation of an extract of tubercle bacilli active in the tuberculin reaction by extraction with water and dilute alkali, precipitation with acid and ammonium sulphate and dialysis.—J. W. MCLEOD and J. GORDON (Leeds) showed that an oxidase test with dimethylparaphenylenediamine was a useful help in isolating the gonococcus, the cholera vibrio, and other bacteria.—C. H. WHITTLE (Cambridge) found types I. and III. of the pneumococcus more virulent than type IV.; all strains isolated from cases of pneumonia, broncho-pneumonia, and empyema were highly virulent.—E. C. LOWE (Liverpool) suggested from his experience that the organism responsible for an infection might be isolated from a mixture by a preliminary incubation in the patient's fresh blood.—W. MAIR (London) described a uniquely virulent strain of *B. diphtheriæ*, the effects of which could not be wholly neutralised by any quantity of diphtheria antitoxin.—J. CRAIGIE (St. Andrews) found that by violent shaking the flagella could be detached from the typhoid bacillus (without killing the organism) and subsequently broken up practically to invisibility; the flagella and stripped bodies each show their characteristic agglutination.—D. NABARRO (London) described his observations on the variability and mutations of dysentery bacilli and the occurrence of anomalous forms in human stools.—F. H. STEWART (Cheddleton) showed variation and papillation in *B. coli mutabilis*; A. H. MILLER (Bournemouth) films of blood and bone-marrow from acute myeloblastic leukæmia; E. H. LEPPER and E. SYLK (London) infarction of the uterus from syphilitic arteritis; E. H. LEPPER and D. CAREW-HUNT (London) a congenital hernia of the diaphragm; M. J. STEWART and A. L. TAYLOR (Leeds) an adenomyoma in a Meckel's diverticulum; G. S. WILSON (London) an improved pattern of McIntosh and Fildes's anaerobic jar; G. S. WILLIAMSON (London) specimens illustrating the development of the lymph system of the thyroid; and C. V. PATRICK (London) thoracopagous twins.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting held on Dec. 15th, the President Dr. J. C. M. GIVEN, in the chair, Mr. R. WATSON JONES read a paper on the

Ritual of Fracture Reduction.

He said that the most valuable—and at the same

time the most ignored—of the many auxiliaries of treatment introduced since the pioneer days of Hugh Owen Thomas and Sir Robert Jones, was radiographic control, now so perfect that plaster and certain metal splints offered no barrier. The modern routine of fracture-reduction must include not only manipulation followed by fixation, but also immediate radiography to determine the position which was being fixed. If this was shown to be imperfect, the routine—manipulate, fix, X ray—must be repeated as often as necessary, on consecutive days, until the position was perfect. Fractures must be regarded as emergencies, and the organisation of a hospital's fracture department should provide for the immediate institution of treatment, with further daily attention until full reduction was secured. The twice-weekly fracture clinic was as obsolete as the once-weekly operating day. The combination of such a routine with control throughout by X rays rendered fracture-reduction simple and certain, and perfect results could be secured, in more than 90 per cent. of recent fractures, by manipulation alone. When operative reduction was necessary intramedullary ivory pegging was the operation of choice, because of the perfect apposition, impaction and alignment ensured. The importance of impaction was seen in the relatively slow union after autogenous bone-pegging. The results of 20 cases of medullary pegging (including 12 from a total of 200 recent and old fractures of the forearm) showed that in the absence of infection union was never delayed, and disappearance of the peg was complete in three to six months.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF SURGERY.

A MEETING of this Section was held on Dec. 16th, 1927. In the absence of the President, Sir WILLIAM WHEELER took the chair.

Bone Pegs.

Mr. WILLIAM PEARSON, in exhibiting some intramedullary bone pegs of his own design, said that the use of ivory or bone pegs was confined to transverse fractures of the shaft of the long bones, without comminution, in which operative treatment was required. The principle consisted in putting the peg into the intramedullary canal so as to keep the two main fragments in alignment while union was taking place. The advantages which Mr. Pearson claimed for his pegs were that they could easily be altered in size by merely filing off the bone, and that they did little damage to the endosteal tissue. To block the medullary canal with a solid ivory or bone peg would retard the formation of callus round the fractured surfaces; therefore his pegs had a series of longitudinal grooves on the surface, and in the larger sizes small central canals, so that callus would growth both through and round the pegs. This avoided a complete block of the medullary canal. It was not a good thing, he thought, to ream out the medullary canal and endosteal tissue, which was most important for bone-formation. The pegs had no elasticity, and as they were made of inert material the sooner they were absorbed the better. The few cases in which he had used them had done extraordinarily well. They were made in six sizes and were obtainable from Allen and Hanbury.

Mr. HENRY STOKES said that he himself had made some bone pegs, but with difficulty and without much success. Using an ordinary chisel he had got a better result by making them not round but octagonal.

Mr. ARTHUR CHANCE said that he found it tedious and rather difficult to alter the pegs themselves; in his experience it was easier to make the bone fit the peg than the peg fit the bone. He was therefore in favour of reaming out the medullary cavity.

Mr. PEARSON, in reply, said that his bone pegs were only for temporary use; they were simply an internal splint to prevent displacement. He would not use them where there was non-union; in such a case the alternative methods were to do a bone-graft or step-cut operation. The latter was feasible in fractures of the humerus.

Typhoid Infection of the Sternum.

Mr. F. J. HENRY recorded the following case.

A man, aged 62, complained of a lump on the front of the chest, which had appeared about five weeks after he had been discharged from hospital, where he had been treated for typhoid fever. There was a smooth, rounded, painless swelling about the size of a golf ball on the anterior chest wall, involving apparently the second, third, and fourth costal cartilages and the right border of the sternum. It was stony hard and very fixed to the deeper structures. A radiogram (lateral view of chest) showed pronounced thickening of the body of the sternum, with osteosclerosis. Exploratory incision was made and the lump found to consist of a fibro-cartilaginous mass, with a central cavity containing pus, from which a pure culture of *Bacillus typhosus* was isolated. No other residues of typhoid infection could be found in urine, fæces, or specimens of bile removed by the duodenal tube.

The frequency of bone complications in typhoid, said Mr. Henry, was said to be less than 1 per cent. This small incidence seemed strange in view of the probability that the marrow of most of the bones was infected sometime or other in most cases of typhoid.

The CHAIRMAN said that this was an interesting and rare case, illustrating one of the fundamental principles in surgery. He referred to the teaching of Murphy that each infection had its own date for metastasis—e.g., the infection from staphylococci appeared 16–21 days afterwards and that from streptococci seven days afterwards. In typhoid metastasis of the bones occurred from the fourth to fifth week after infection. The fact that each organism and each disease had its own date for metastasis considerably simplified the subject for teaching purposes.

Mr. CHANCE said he had had a case similar to Mr. Henry's. The patient came to him five months after having typhoid fever, with an indolent, inflammatory swelling in the right side of the sternum. A little thickened pus was obtained on incision. The rib cartilage was bare, but there was no evidence of necrosis. Healing occurred in six weeks.

Mr. STOKES quoted two similar cases in his experience. In one there was an abscess in the tibia; in the other an abscess in the back of the scalp. Both had healed up without the slightest difficulty. His experience in these two cases made him incline to the view that it was advantageous to open the bone and scrape it right away.

Mr. HENRY, in reply, said that in a similar case of swelling, occurring four to five weeks after the infection, he would leave it alone. Infections in bones other than the ribs and sternum healed up without much difficulty. The reason for difficulty in this case was that it was extremely hard for the soft parts to collapse into it. If the cavity did not heal up he proposed filling it with a muscle graft from the pectoralis major.

Spinal Caries.

The CHAIRMAN read a communication on the results of the treatment of Pott's disease by conservative treatment and by conservative treatment supplemented by bone-grafting. It was too soon, he said, to know the results of the admirable modern methods of treatment in open-air hospitals, with specially skilled assistants and trained orthopædic nurses. Under the old régime, however, the results following treatment in city hospitals, without special nursing and with inadequate methods of fixation, were far from satisfactory. A review of the figures given by different authorities suggested that very few cases of advanced Pott's caries ever reached old age. Some figures showed that within a period of 12 years 40 per cent. were dead; other authorities gave the percentage of deaths within 15 years at 38·6 and others at 40·5. 75 per cent. of the deaths occurred within the first two years. Fusion operations of the spine had been introduced in 1911 and surgeons of experience generally agreed that the bone-grafting operation was a distinct addition to the armamentarium of the general as well as the orthopædic surgeon. There was no

doubt whatever that both the Hibbs and the Albee operations caused fusion of the laminæ. This had been proved by cases which needed a second operation, by post-mortem examinations, by clinical observation, and to some extent by radiography. Sir William Wheeler urged the necessity of careful and prolonged after-treatment. His own practice was to keep the patients on a Thomas or Jones frame for three months and then to keep them in bed for three months without the frame. For another three months they were allowed to move about carefully wearing a Jones posterior spinal support night and day, and afterwards the spinal support was continued according to the progress made. He had never seen, in an adult, the absorption or disappearance of a bone-graft after introduction. Personally he was against operation in the case of children. He had operated upon several young children about 12 years ago and was satisfied that the method was not justified unless in exceptional cases. A number of surgeons advocated the operation as part of conservative treatment in young children, and had proved conclusively that the introduction of the graft did not interfere with the growth of the child. The presence of an abscess or paraplegia was, in his opinion, a strong indication for the introduction of a graft.

Discussing treatment and prognosis when paraplegia was present, Sir William Wheeler said that in his view laminectomy did more harm then good. Frazer's operation to relieve pressure was designed on sound principles. After referring to the various operations for spinal fusion he gave an account of 30 adult patients treated in the ten-year period 1917–27. Of these six had died; 19 or 20 appeared to be cured.

Mr. FREDERICK GILL said that with a bone-grafting operation the patient was restored to his normal strength in a shorter time than with conservative treatment, and he was able to carry on for a number of years. During the operation he used local as well as general anæsthesia. The skin and spinal muscles were anæsthetised with novocaine and adrenalin, and this, he believed, lessened the shock, reduced the loss of blood to a minimum, and made the operation easier by rendering the field almost bloodless. He used an osteotome or chisel for cutting the graft in preference to the Albee saw, which, he thought, cauterised the bone and was apt to destroy the osteoblastic tissue.

Mr. T. J. D. LANE, Mr. A. B. CLERY, and Mr. CHANCE also spoke and Sir WILLIAM WHEELER replied.

Ununited Fracture.

Mr. WILLIAM DOOLIN showed a man, aged 63 years, who had broken both bones of the forearm 16 years ago. There was a false joint with very poor grip; both pronation and supination were present, but only to a limited extent, and the patient could not lift weights. Owing to his age and extensive sclerosis of the bone-ends Mr. Doolin had decided against operative repair. A celluloid armlet had been made to control the forearm, abolishing the flail movement; and with this the patient's gripping power was definitely improved; he could now lift a chair held out at arm's length.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A MEETING of this Society was held in Manchester on Dec. 16th, 1927. An address on the Present Position of Gynæcology was given by Prof. FLETCHER SHAW, the President, who took the chair.

Prof. MILES PHILLIPS (Sheffield) showed a specimen of

Hydrops Tubæ Profluens.

The patient, a 6-para aged 42, complained of attacks of pain in the right lower abdomen, lasting 2 to 7 days at intervals of 3 to 6 weeks. She said that a swelling, about the size of an orange, formed on the right side when the pain was severe, followed by a gush of thin bluish fluid from the vagina when the pain ceased and the swelling disappeared. The same thing occasionally happened on the left side. Nine months after the last confinement, 14 years ago, she had inflammation of the womb and ovaries. Menstruation lasted 2 to 7 days and came on every 24 to 26 days. There had been increased loss during the last 13 years. The patient had a constant greenish-yellow discharge, but no vulvitis. There were indefinite adnexal swellings. At operation a bilateral hydrosalpinx was found, larger on the left side, and the uterus and both appendages were removed. When a piece of silkworm-gut was passed through the uterus into the tubes clear fluid ran out. The cavity of the hydrosalpinges did not communicate with the cystic ovaries.

Prof. ARCHIBALD DONALD said there might be a valve action at the uterine end of the tube. He had never known pus thin enough to escape.—Dr. K. V. BAILEY had seen a patient with a large right hydrosalpinx who had had an intermittent discharge for 18 months—Prof. BLAIR BELL (Liverpool) said that he had noted an intermittent discharge as a rule in malignant disease of the tube.—Dr. J. H. WILLETT (Liverpool) suggested that the rise of tension could sometimes overcome the retention of fluid, and asked if there were any adhesions.—Prof. PHILLIPS, in reply, said there were no adhesions and likened the retention to urinary retention with overflow.

Dr. E. O. CROFT (Leeds) showed a specimen of

Ruptured Isthmial Pregnancy.

The patient was a 2-para aged 40. She had had amenorrhœa for six weeks with prodromal pain for a week or two, and then an acute attack of pain just before admission. On laparotomy the tube was found to be merely attached by the mesosalpinx, having been severed completely from the uterine cornu. The ovum was embedded in the tube just at the junction with the uterus, and when it burst had caused complete detachment of the tube.

The PRESIDENT was surprised to hear of the prodromal pain and asked its cause.—Prof. DONALD thought that the term "burst" was inappropriate. The tube had not been dilated. Rupture was always due to erosion of the tube wall.—Prof. PHILLIPS believed that erosion of the tube took place. He had seen a case in which the hole in the tube was so small that it had been missed at operation and was only found at autopsy.—In reply, Dr. CROFT said that he believed that in most cases of ectopic gestation rupture was due to erosion of the tube wall. The prodromal pain was not severe, and he was unable to account for it.

Dr. CROFT also showed a specimen of

Pseudo-elephantiasis of the Vulva.

A 2-para, aged 22, complained of swelling of the vulva gradually increasing for 12 months and causing inconvenience. The whole vulva was greatly enlarged and thickened, and on the left side a pendulous mass about 5 inches in diameter was hanging from a stalk formed by the labium minus. The Wassermann reaction was negative, and the vulva was completely excised.

Dr. F. H. LACEY said he had seen several cases of pseudo-elephantiasis at a venereal clinic and had cured them with 2 per cent. lactic acid.—Mr. J. E. STACEY (Sheffield) had also seen a number of similar cases, and asked if there was any thickening of the vessels in the specimen to corroborate the theory of a syphilitic ætiology.—Dr. CROFT, in reply, said that no arterio-sclerosis was noted.

Prof. D. DOUGAL read a note on

Three Cases of Hæmatometra Associated with Tuberculosis.

CASE 1.—A woman, aged 37, had been married for seven years. There was primary amenorrhœa till she was 30 and since then a slight loss every five to six weeks. Poor health. As a child she was an in-patient at a children's hospital for a month. The uterus was enlarged to about the size of a four months' pregnancy; the appendages were adherent and panhysterectomy was performed. The uterus had a single cavity containing blood. The left tube was also distended with blood. No communication could be made out between the uterine cavity, the cervical canal, and the right tube. Microscopical examination showed an adenomyomatous condition of the right uterine cornu, and necrotic areas with giant cells.

CASE 2.—Patient, aged 31, married two years. Primary amenorrhœa. "Consumption of the bowels" when a baby. Pain in lower abdomen for ten years. The uterus was enlarged, size of two months' pregnancy, hard and fixed, and there were adhesions in the pelvis. Subtotal hysterec-

tomy with removal of both appendages was performed. The uterus contained two cavities, the larger on the right side and communicating with the right tube, which was closed at its outer end. The left tube was closed except in the interstitial portion, and showed chronic interstitial salpingitis. Microscopically necrotic areas and giant-cells were seen.

CASE 3.—Patient aged 22; single. Primary amenorrhœa. History of phthisis in family. Uterus enlarged and cystic. Had an acute attack of pain while awaiting admission to hospital; treated by appendicectomy. The uterus, removed by subtotal hysterectomy, was asymmetrical, the right half being larger than the left. There were two cavities, the right containing blood and the left containing pus with necrotic material and giant cells.

All three specimens, said Prof. Dougal, showed atresia associated with chronic infection. The question was whether the chronic infection in early life was or was not the cause of maldevelopment. He was inclined to think it was.

Prof. PHILLIPS believed that a condition of obliterative endometritis developed in the region of internal os. He had once reported a hydrometra the size of a seven months' pregnancy due to tuberculosis.

Miss FRANCES IVENS (Liverpool) had had a case of a single woman who developed amenorrhœa after normal menstruation. The uterus reached the umbilicus and was filled with blood. The obstruction was at the external os, and there was no evidence of tubercle. She described another case in which there was caseous material in the cavity. She curetted it away and the patient afterwards menstruated.

Dr. LEITH MURRAY (Liverpool) had had two cases in which he established communication between the hæmatometra and the cervix with a curette.

In reply, Prof. DOUGAL said that none of his specimens showed infection of the lower part of the uterine wall.

MANCHESTER MEDICAL SOCIETY.

AT a meeting of this Society, held on Dec. 7th, 1927, Dr. J. GRAY CLEGG delivered a presidential address on

Ophthalmology in Relation to General Medicine.

The embryology of the eye, he said, is interesting, because it shows a fourfold relation with ectoderm—by the neural ectoderm of the retina, the lens, the conjunctiva, and the skin of the lids. Important structures such as the uveal tract and the cornea are of mesodermic origin. It is not surprising, therefore, that the eye shares with ectodermic and mesodermic organs disturbances of function and nutrition. Again, its anatomical relations, its nerves and blood-vessels, together with the visual pathways, are so complicated that affections of the brain and spinal cord are very apt to set up and produce important signs. Thus, on the one hand, the ophthalmologist must have a wide knowledge of anatomy, physiology, and pathology, and on the other, the physician should be familiar with methods of examining the eye. Every medical man should possess a good lamp, a large lens of 3 inches focal length, a pocket loupe, and an electric ophthalmoscope.

Dr. Clegg went on to describe the signs of retinal arterio-sclerosis and its relation to general arterio-sclerosis. It is recognised, he said, by the "copper-wire" appearance in the early stage, and by the "silver-wire" appearance when the lumen has become completely occluded. Serious cerebral results follow in about 45 per cent. of the cases in which this condition has developed. Amaurosis fugax may result from temporary spastic occlusion of the retinal arteries, but if the blood stream is long stagnant, thrombosis sets in and the result is coagulation-necrosis of the retina. Many cases formerly regarded as embolism of the central retinal artery or one of its branches are really due to this cause. Thrombosis of the retinal vein brings about rapid loss of sight, is evidenced by extensive hæmorrhages, and is often complicated by a secondary glaucoma. The appearances of renal retinitis, said Dr. Clegg, are characteristic, but not pathognomonic; it occurs in one-third to half the cases affected by contracted kidney. In chronic parenchymatous nephritis, the retina is usually unaffected. When renal retinitis is present the blood pressure is almost always high. The condition may occur at any age, whereas arterio-sclerotic retinitis is a disease of old age. Very few cases survive for two years after renal retinitis is discovered, whereas patients with arterio-sclerotic changes may live much longer. In renal cases both eyes are usually affected, but in nearly half the cases of arterio-sclerosis the signs are unilateral. Papill-œdema may occur as the only ocular sign in renal disease, and then differential diagnosis from a cerebral tumour may be difficult; the blood pressure is a distinct guide. It is believed that there are two outstanding factors producing different types of renal retinitis—viz., toxic and vascular—and that in parenchymatous nephritis the toxic element prevails, whereas in the small red kidney the vascular is the more important. There is reason to suppose, Dr. Clegg continued, that the retinitis of diabetes is really due to the disease and not to the concomitant renal condition. Diabetes also affects the pars retinæ iridis, and Harrison Butler states that he has diagnosed diabetes from an œdematous condition of the mamelons, the brown knobs at the pupillary margin of the iris. The lens may become opaque, and there may be rapid changes in its refractive index; in fact, if a form of progressive myopia is noted in an elderly person diabetes is almost always the cause of it. The central scotoma for colour in cases of diabetes, he considers, may really be an effect on the ganglion cells of the macular region, as in tobacco amblyopia.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

AT a meeting of this Society held on Jan. 5th Dr. DONALD HALL, the President, took the chair and Mr. G. W. BERESFORD read a paper on

Gastric Ulcer.

The treatment of duodenal ulcer by gastro-jejunostomy was, he said, more or less generally accepted. Gastric ulceration was a more serious disease, and the treatment presented a difficult problem. The most important contributory causes were unsuitable and irritating foods; perhaps the increased consumption of sugar, leading to gastritis; mental over-exertion and worry, causing an upset in the innervation of the stomach; and focal infection from the teeth or intestinal tract. Acute ulceration was less common than it had been 10 or 12 years ago. The tendency was towards early healing and treatment should be entirely medical; even severe hæmorrhage was not an indication for surgical intervention. Chronic gastric ulcers were generally situated along the lesser curve, probably because of the lymphoid follicles in this region. The main symptoms were periodicity of attacks of epigastric pain and vomiting, coming on one, two, or three hours after food. Radiography was the only certain means of diagnosis. Hæmatemesis was not usual, but was of serious import. Bulmer's recent figures [1] showed that the mortality from hæmatemesis was very high. Medical treatment should be given in all cases except where there was a suspicion of carcinoma, where a course of such treatment had already failed, where there had been an attack of hæmatemesis, or in the presence of perforation or mechanical deformity of pylorus or stomach. In these exceptional cases surgical treatment was to be adopted. Medical treatment should consist of Sippy's diet with a suitable period of rest in bed. The aim of surgical treatment was to remove the chronic infection of the stomach wall and to eliminate free HCl. Gastro-jejunostomy, together with excision or cauterisation of the ulcer, should be adopted for non-adherent ulcers, whilst large and fixed ulcers should be treated by subtotal gastrectomy.

Reviews and Notices of Books.

ANTITUBERCULOSIS VACCINATION.

La vaccination préventive contre la tuberculose par le "B. C. G." By A. CALMETTE, Sub-Director of the Pasteur Institute. With the collaboration of C. GUÉRIN, A. BOQUET, and L. NÈGRE. Paris: Masson et Cie. 1927. Pp. 250. Fr.22.

IN this book Prof. Calmette has brought together the main details of the publications which he and his collaborators have made from time to time in scientific journals, notably the Annals of the Pasteur Institute, dealing with prophylactic vaccination against the tubercle bacillus. These papers cover a long period, and it is no small advantage to have the material, which has hitherto been scattered over many journals, brought together in this way. Of the four parts into which the book is divided, the first is devoted to a summary of the various experiments on antituberculosis vaccination made since the discovery of the bacillus, a good deal of which is reprinted verbatim from Calmette's book on Bacillary Infection. The second part is concerned with the researches made upon cattle, especially young calves, and of the tests made in collaboration with Dr. R. Wilbert on the protection of apes in the tropics by means of prophylactic vaccination. This work is already well known. The third part is a record of laboratory work, cultural, immunological, and histological, with the bovine strain of tubercle bacillus known as B.C.G., first isolated in 1906, and repeatedly subcultured for 13 years on a special medium of glycerinated ox-bile until its virulence was reduced to the point of safety for inoculation work with living cultures. This part of the work is the crux of the whole inquiry. The fourth and last part summarises the results of prophylactic injections of B.C.G. vaccines given to infants since 1921, including the statistics (published in the Annals) for the Seine Inférieur which are the best documented. Most of this work has already been reviewed in our columns during the last two years.[1] The book closes with the reproduction of a set of model forms used in the statistical inquiry work with prophylactic vaccination of infants in France. There is also a serviceable bibliography, but, as too usual in French scientific books, no subject index.

THROAT, NOSE AND EAR.

Diseases of the Throat, Nose and Ear. Second edition. By DAN MCKENZIE, M.D., F.R.C.S.E., Surgeon to the Central London Throat and Ear Hospital. London: William Heinemann (Medical Books), Ltd. 1927. Pp. 677. 45*s.*

THE second edition of this book, which appears seven years after the first, has been very considerably enlarged, and maintains the high standard set by the original work. It is one of the class of large text-books which deals with laryngology and otology in a full and complete manner. It will be valuable to the young specialist wishing to complete his knowledge of these subjects, and useful as a work of reference both to the established oto-laryngologist and to the general practitioner. The general plan of the book remains unaltered in the new edition, but numerous additions have been made. Among these are a series of pictures after Laurens illustrating the operation of laryngectomy; it is perhaps to be regretted that the Glück type of operation, from above downwards, is not described, for it has made considerable headway in this country and possesses several advantages. The limits of laryngology are difficult to define, but it seems inadvisable to discuss goitre in a work of this kind, at any rate unless diseases of the thyroid gland are fully described; we are glad to see that the description and illustrations of the operation of thyroidectomy have been omitted from this edition. The short article on cleft-palate is inadequate, and might equally well have been left out; on the other hand, the final chapter on the lymphatic glands of the neck, with hints on dissections in this region, will be most useful to the laryngologist. The book is well and profusely illustrated, and may be cordially recommended.

[1] THE LANCET, 1926, i., 1030, 1046; and 1927, i., 936.

Handbook of Diseases of the Nose, Throat and Ear. For Students and Practitioners. Second edition. By W. G. SYME, M.D., F.R.F.P. & S. G., F.R.S.E., Surgeon for Diseases of the Throat and Nose, Western Infirmary, Glasgow, and to the Ear, Nose and Throat Hospital, Glasgow. Edinburgh: E. and S. Livingstone. 1927. Pp. 396. 12*s.* 6*d.*

THIS little book has been written primarily for students in the hope of stimulating their interest in the specialty. As Dr. Syme says, students are apt to look upon diseases of the nose, throat and ear as of little importance for the passing of examinations, and it is only when they start practice that they realise how often affections of these regions will engage their attention. Dr. Syme's book will doubtless fulfil its purpose, for it is well written in an interesting manner; the matter is presented on sound lines, and the recommendations on treatment are sensible. In a future edition the author might well consider the advisability of adding more illustrations of pathological conditions, especially in the nose and throat, for pictures are of great assistance to the young practitioner in recognising lesions.

Diseases of the Nose, Throat and Ear. For Practitioners and Students. Second edition. Edited by A. LOGAN TURNER, M.D., LL.D., F.R.C.S.E., Consulting Surgeon, Ear and Throat Department, Royal Infirmary, Edinburgh. Bristol: John Wright and Sons, Ltd. 1927. Pp. 440. 20*s.*

THE history of this text-book is of interest. It has been evolved from a much smaller text-book written by Dr. W. G. Porter in 1912, a second edition of which was revised and published by Dr. P. McBride during the author's absence on active service. Dr., then Major, Porter, D.S.O., was killed in action in 1917, and his friends and colleagues in Edinburgh, headed by Dr. Logan Turner, revised a third edition as a labour of love and a tribute to his memory. This was perpetuated in a larger work published, under the editorship of Dr. Logan Turner, in 1924, which has now reached a second edition. The section on diseases of the nose is under the joint authorship of Dr. Logan Turner and Mr. W. T. Gardiner, the former being responsible also for that on the paranasal sinuses. Mr. Douglas Guthrie deals with the pharynx and nasopharynx, Mr. J. D. Lithgow with the larynx, Mr. G. E. Martin with endoscopy, and Mr. J. S. Fraser with diseases of the ear. The work is an important one, and gives an admirably clear and concise account of diseases of the specialty. Since it is written primarily for students and practitioners, methods of examination are carefully detailed, but the larger operations are not fully described. The numerous excellent illustrations add to the value of the book.

Practical Guide to Diseases of the Throat, Nose and Ear. For Senior Students and Junior Practitioners. Fifth edition. By WILLIAM LAMB, M.D., C.M. Edin., M.R.C.P. Lond., Consulting Surgeon, Birmingham Ear and Throat Hospital. Revised by FREDERICK W. SYDENHAM, M.D., C.M. Edin., F.R.C.S.E., D.P.H. Vict., Honorary Surgeon, Birmingham Ear and Throat Hospital. London: Baillière, Tindall and Cox. 1927. Pp. 450. 12*s.* 6*d.*

THE arrangement of this little book is somewhat unusual; the method has been to devote a chapter

to examination of a region, such as the nose, followed by a chapter on its treatment. The mouth and pharynx are thus dealt with, and then in turn the nose, the larynx, and the ear. A disadvantage of this method is that a series of diseases is described in one chapter and the treatment appropriate to each discussed in another; this leads to confusion and overlapping occurs which would be avoided with a simpler arrangement. A paragraph on congenital laryngeal stridor on p. 253 appears to have become mixed up with a description of tracheotomy, which latter has no beginning and does not appear in the index. The concluding chapter is devoted to Dr. Sydenham's experiments on radiography of the skull, with 29 skiagraphs, mostly of dry specimens; this chapter would form a monograph on some aspects of the technique of radiography, but is out of place in a short guide to oto-laryngology. In spite of these defects the book contains a good deal of useful information and much sound advice.

ACTINOTHERAPY.

Ultra-violet Rays in the Treatment and Cure of Disease. Third edition. By PERCY HALL, M.R.C.S. Eng. London: William Heinemann (Medical Books), Ltd. 1927. Pp. 236. 12*s.* 6*d.*

THERE is still a widespread impression that treatment by ultra-violet light is a simple and harmless proceeding, and much ignorance as to which of the various forms of lamp now on the market do actually give off ultra-violet rays. Dr. Hall's book, which passed rapidly through two editions in 1924–25, was published with the definite object of combating erroneous views. The present edition has been largely rewritten and has greatly increased in size. In its present form it should be useful to the many doctors who are taking up this form of therapy. Curiously enough, however, one of the main questions upon which they might reasonably look for some information—namely, dosage—here receives but scanty attention. The author is content simply to say (p. 127): "Each patient is a law unto himself, and every case requires careful individual consideration, and must be judged on its own merits. This is the only safe and scientific method of estimating dosage in actinotherapy." But this statement is not very helpful to anyone seeking information on how to measure the yield of radiation from the source he is using or what doses are generally suitable in certain varieties of disease. Dr. Hall states that results are occasionally gained by the use of the tungsten arc, which cannot be achieved with other types of lamp, a fact which he ascribes to the richness in quality and quantity of its emanations (we must ask, in passing, is radiation an emanation?), and he suggests that the tungsten spectrum includes wave-lengths whose presence cannot be detected by any modern spectroscope or other instrument. He is led to assume that the ultra-violet rays of the fifth octave are not less, but more, penetrating than those of the first octave. In making such assumptions as these he seems to overlook the vacuum spectrometer as an instrument of precision.

BASAL METABOLISM.

Basal Metabolism in Health and Disease. Second edition. By EUGENE F. DUBOIS, M.D., Medical Director, Russell Sage Institute of Pathology; Associate Professor of Medicine, Cornell University Medical College. London: Baillière, Tindall and Cox. 1927. Pp. 431. 22*s.* 6*d.*

THE estimation of basal metabolism has become of increasing importance during the last few years, both in research and in practical medicine. Dr. Dubois, the second edition of whose book has been revised and brought up to date, approaches the subject in a manner interesting both to clinician and physiologist. The first part deals with normal metabolism. With regard to the choice of apparatus, the author points out that many types are accurate and efficient, and errors lie more often in the operator than in the apparatus. Every worker must attain complete mastery of his own instrument, and be aware of its sources of error; this implies that he must study a large number of normal individuals before investigating the abnormal. The Benedict unit, Zuntz-Geppert apparatus, Tissot spirometer, and Douglas bag, in experienced hands, give identical results, which in turn agree with those obtained in a respiration calorimeter. In this edition the chapter on the estimation of the surface area of the body has been rewritten, and the results obtained by different methods are compared. The influence of age, growth, and diet on normal metabolisms are also discussed. The difficulties in the selection of normal standards for comparison are great; every piece of work involves the study, with exactly the same technique, of a large number of normal controls in order to ascertain directly the correct standards for the given conditions.

The second part of the book deals with basal metabolism in disease and contains chapters on undernutrition, obesity, disease of the thyroid and ductless glands, cardiac and renal disease, fever, nervous diseases, and water metabolism. To the clinician the chapter on thyroid diseases is of most interest, for here basal metabolism tests have the greatest practical value. In discussing their reliability the author points out that although such tests form the best available measure of activity in the thyroid gland, they must not be accepted blindly. For example, emaciation and inanition in hyperthyroidism may counteract a raised metabolism and make it appear normal. In spite of such difficulties, basal metabolism tests are shown to be of great value, especially in estimating progress before and after operation or during iodine or other treatment. Throughout the book frequent references are made to original work in sufficient detail to enable the reader to weigh evidence himself and form his own conclusions on controversial points.

The book is well indexed and illustrated, and supplies a full and valuable summary of our present knowledge of basal metabolism.

Le métabolisme basal. Les applications en clinique. Par CLAUDE GAUTIER, Médecin des Hôpitaux de Paris; et RENÉ WOLFF, Chef de Laboratoire adjoint à la Faculté de Médecine de Paris. Paris: Gaston Doin et Cie. 1928. Pp. 172. Fr.15.

THIS little book deals with the subject of metabolism from the point of view of the clinician and discusses the practical value of basal metabolism tests in diagnosis and prognosis. The first and larger part deals with metabolism in health; this part includes an outline of the principles of the production and conservation of animal heat and the effects of muscular work and digestive processes on heat production. The constancy of the minimal heat production in the same and different normal subjects is discussed, with the allowance to be made for variations in weight, height, age, and sex. Details of laboratory technique are not given, but the principles of direct and indirect calorimetry are outlined. A short chapter is devoted to the effects of drugs on basal metabolism in normal people. The second part deals with metabolism in disease. The authors consider the basal metabolism test is of greatest practical value in diseases of the endocrine organs and especially of the thyroid gland. In these it is very useful in mild cases of hyperthyroidism and hypothyroidism when clinical evidence is insufficient. It is valuable in estimating the course of these conditions so that treatment can be more accurately regulated. In the diagnosis of certain disorders of the pituitary gland, the genital glands, and in diabetes mellitus the test also finds a place. The book concludes with a bibliography of the more important literature on the subject. For the clinician it forms a useful introduction to the modern studies of basal metabolism.

ABDOMINAL SURGERY.

Surgical Diseases of the Gall-bladder, Liver and Pancreas, and their Treatment. By MOSES BEHREND, A.M., M.D., F.A.C.S., Attending Surgeon to the Jewish and Mount Sinai and Northern Liberties Hospitals; Instructor in Anatomy, Jefferson Medical College. Philadelphia: F. A. Davis Company. 1927. Pp. 278. $4.

OF this small book 117 pages are devoted to the anatomy and physiology of the liver and pancreas. There follows a chapter upon pathology. Neither in this chapter, nor in the rest of the book, is any new light thrown upon the subject, nor is the work which has been done in the past systematically reviewed. The author emphasises his own custom of removing the gall-bladder only after exposing to view the structures in the right margin of the gastro-hepatic omentum, but is unfair to the majority of surgeons (at least English and European ones) when he states, p. 176, "The operation of cholecystectomy is almost invariably performed by most surgeons within the gastro-hepatic omentum by the so-called 'closed' method," and "little cognizance of the proper method of removal of the gall-bladder" (meaning dissection of the cystic and bile-ducts as the first step) "has been taken." There are no statistics of the author's own results (though some interesting case-histories are told) and many omissions. The accounts of the experience of other surgeons are inadequate.

NOTES ON CLINICAL LABORATORY METHODS.

By the Standing Committee on Laboratory Methods of the University of Glasgow. John Smith and Son (Glasgow), Ltd. 1927. Pp. 66. 2*s*.

THIS book represents the result of the labours of a committee appointed by the University of Glasgow to secure uniformity in the laboratory methods used in the clinical teaching in the department of medicine of the University. The field covered is equivalent to side room testing as usually carried out by students of medicine. In addition, much useful information is included as to the correct method for the collection and transmission of specimens requiring somewhat more elaborate methods of investigation than those included in the book. The book is well suited to its purpose, and will also prove useful to medical men who wish to perform for themselves the simpler methods of laboratory investigations.

PHYSICAL DIAGNOSIS.

Ninth edition, revised and enlarged. By RICHARD E. CABOT, M.D., Professor of Medicine in Harvard University; formerly Chief of the West Medical Service at the Massachusetts General Hospital. London: Baillière, Tindall and Cox. 1927. Pp. 536. 25*s*.

As an aid to diagnosis in practice this book is valuable, because the author has only included technique which he himself has tested by long trial and found reliable enough to recommend to others. Useful methods of examination are thus not obscured by others which, though they have long since fallen into disrepute, still lumber up the pages of many otherwise trustworthy books. Many time-worn but useless diagnostic "signs" are not even mentioned. Of Kernig's sign the author says: "This reflex is of some value in the diagnosis of meningitis, though allowance must be made for the stiffness of old age. The sign is by no means pathognomonic, but is of some confirmatory value." Such a statement puts the test in its proper place. The proportionate value to be placed on positive and negative findings is stressed throughout the book. Methods of examination of the central nervous system are only dealt with briefly. The exact localisation of lesions is not attempted, the reader being referred to larger works on the subject. The sections on tuberculosis, the blood, and cardiovascular disease have been revised. Reference numbers are included to the Gamble-Cabot cardiac diagnosis records, a set of phonographic records taken of normal heart sounds, the third heart sound, and various types of murmur and irregularity. The illustrations are clear, and these by themselves are of value in diagnosis.

This new edition should be welcomed by students and physicians.

CHEMISTRY OF FAMILIAR THINGS.

Fifth edition, revised and enlarged. By SAMUEL SCHMUCKER SADTLER. London and Philadelphia: J. B. Lippincott Company. 1927. Pp. 336. $3.

THIS is a useful book, for its main object—namely, to point out how many of the things which the average person sees about him are really a demonstration of chemistry—is well carried out. We have here, in fact, a synopsis of the most important recent developments related to chemistry as that science enters daily life, and the unscientific reader is thus enabled to obtain the sort of accurate knowledge which should enable him to understand the forces involved in phenomena with whose externals he is perfectly familiar. The subjects dealt with, after a brief outline of the divisions under which the workings of chemistry manifest themselves, include light and heat, air and water, various metals, soil, food, and the application of chemistry to the several arts and manufactures. The book is already widely appreciated, as its regular reissue testifies, and a chapter entitled Chemistry since the War brings it up to date.

THE EARLIER INHABITANTS OF LONDON.

By Prof. F. G. PARSONS, F.R.C.S., F.S.A. London: Cecil Palmer. 1927. Pp. 240. 10*s*. 6*d*.

THIS book is a delightful combination of osteology, archæology, and history, and for Londoners in particular it will have great attractions. It is the result of many years' work on the physical anthropology of the inhabitants of this island, and the author wisely warns us that the historian should understand clearly how little as well as how much help he may expect from anthropology in its present state. According to Prof. Parsons, there has been no continuous occupation of London since the days of the old Stone Age, the present contours of gravel and river drift having been deposited since that date, while he points to the geological estimate that the twin hills which form the site of the city rose for the first time from the river bed about 3000 B.C. At this date probably the surrounding country, densely afforested, was largely occupied by a race which had migrated slowly westward along both shores of the Mediterranean, occupying the various peninsulars, and getting as far as Great Britain by turning up through Spain. The London history of paleolithic and neolithic man is set out mainly in terms of the skeletons and especially the skulls found in the "long barrows"—the earliest method of sepulture—and the next irruption from the continent appears to have occurred a thousand years later. The origin of this is unknown, but the migrants were tall and round-headed, and their influence upon the population is thought to have been slight. On the arrival of the Nordics, however, about 600 B.C., real and obvious changes were produced in the racial make-up, owing in particular to the difference in pigmentation and the well-shaped nose of the Nordic race. While a gradual evolution was thus taking place among the earlier inhabitants of our islands, London for practical purposes was not existent. It did not start as a city until after the Roman invasion, and has no record until it became a suitable port for the city of Verulam, which stood a few miles from St. Albans. From this point onwards the reader is on more familiar ground and will enjoy Prof. Parsons's epitome of what may be learned from nature and physical anthropology concerning the characteristics of the various races which lived around the site of London before any settlement was effected, as of those who were the first inhabitants.

THE LANCET.

LONDON: SATURDAY, JANUARY 14, 1928.

THE TREATMENT OF THE MALARIAS.

QUININE has certain disadvantages. It is expensive, it has a bitter taste, large doses are often required, and it does not at once remove from the cutaneous circulation the gametocytes which infect anopheles. Hence has arisen a search for substitutes, of which plasmochin is a recent example. More than a year has elapsed since the first full reports on this synthetic drug were published by MÜHLENS and his collaborators,[1] and enough observations have accumulated to draw some fairly sure conclusions about its uses and dangers. That both exist cannot be doubted. Even in the original communication [1] SIOLI reported that cyanosis and jaundice sometimes appeared if the daily dose of 0·08 g. (taken in three-day courses, with three-day intervals, for two to three weeks) was raised to more than 0·1 g. Indeed, one man who took 0·08 g. daily for eight days developed hepatic pain, ashen cyanosis, collapse on exertion, and chocolate-coloured blood, methæmoglobinæmia and methæmoglobinuria both being present. MÜHLENS, who laid chief stress on the drug's destructive action on crescents, at that time dismissed cyanosis, occurring with daily doses of less than 1·0 g., as an unpleasant vasomotor and neuropathic effect. That the cyanosis of plasmochin-administration is due to methæmoglobinæmia was, however, demonstrated spectroscopically by MANSON-BAHR before the Royal Society of Tropical Medicine and Hygiene last year. FISCHER and WEISE,[2] examining the blood of 26 patients receiving 0·05 to 0·1 g. daily, found methæmoglobinæmia in 25, the percentage ranging from 4 to 20. Percentages of more than 4 were found in 10 out of 13 cases on a daily dose of 0·03 g., but were deemed harmless; the higher percentage occurred on a dose of 0·1 g., cyanosis being so great that quinine had to be substituted for plasmochin. Nevertheless, MÜHLENS, although he now admits that plasmochin causes methæmoglobinæmia, still holds that with a daily dose of 0·01 g. per 10 kg. of body-weight (or 0·07 g. for a man of ordinary size) there is no more risk with this drug than with quinine or salvarsan. This view cannot be accepted. EISELSBERG [3] reports upon a medical man receiving this dosage (10 tablets, or 0·2 g. in about three days) who collapsed with methæmoglobinæmia, fever, vomiting, and great hepatic tenderness. He had an enlarged spleen, the red corpuscles were reduced to 1,550,000 per c.mm., the serum was tinged with bilirubin, and his life was only saved by blood transfusion.

If, as seems necessary, the dosage of plasmochin must for safety be reduced to 0·03 g. daily in accordance with the experience of SIOLI and EISELSBERG and the work of FISCHER and WEISE, the results obtained by those who have used higher doses must be disregarded. And they comprise almost the whole experience with the drug. FISCHER and WEISE, however, have reported on the effects of the smaller doses and found that so far from causing the disappearance from the cutaneous blood of schizonts of subtertian malaria, the plasmochin acted rather as a provocative; they describe multiplication of subtertian rings and precipitation of an acute attack, so that recourse to quinine was needed to cut it short. With the reduced dosage it was noted that crescents disappeared from the cutaneous circulation always within 10 and usually within five or six days. Unfortunately, however, the action of plasmochin on crescents cannot be depended on. Their disappearance may be merely temporary, and BÄRMANN and SMITS[4] report that under four plasmochin tablets (0·08 g.) daily they have followed a case in which crescents actually appeared for the first time in the cutaneous blood after administration of the drug had continued for five days. It may be mentioned that the figures illustrating the degeneration of crescents after exhibition of plasmochin obtained by MANSON-BAHR [5] followed daily doses two to four times as large as those which the observations we have quoted seem to permit for the future. On both sides of the Atlantic there have been deaths which it is unreasonable not to attribute to plasmochin, and the conclusion seems inevitable that results obtained with the dosage advised and in general use must be discounted, and that the whole matter must be reinvestigated, using the quantities which FISCHER and WEISE suggest. In weighing the evidence one further source of error should also be borne in mind. Plasmochin is issued in tablets of two kinds: first those containing merely 0·02 g. of plasmochin, and secondly those containing 0·01 g. of plasmochin plus 0·125 g. of quinine, known as plasmochin-compound. In reports on the effect of plasmochin-compound—and they are numerous—too little stress may be laid on the fact that the man who is taking the advised dose of 0·08 g. of plasmochin is also taking, anonymously, grs. 15 of quinine.

These and other investigations, although suggestive, do not permit the conclusion that any known drug is capable of replacing the crystallisable alkaloids of cinchona in the treatment of malaria. Stovarsol, for example, is without effect on the quartan and subtertian forms, and cannot be relied on to banish even the tertian parasite more than temporarily. It is not to be expected, either, that these new drugs will lower the cost of malarial treatment—a matter of extreme importance to the many millions of impoverished persons implicated. How, then, can this cheapening be brought about? The present position appears to be as follows. There is no shortage of cinchona-bark or of quinine as bark, but not enough quinine is being extracted in Java to meet the world demand, of which Java supplies about nine-tenths; there is merely a shortage of quinine at a price which would make it available for general tropical use. Only in Java have the quinine-rich species of tree flourished under cultivation; the high quinine-content of these trees is a result of careful selection, and so long as quinine is used in malaria to the exclusion of the other crystallisable cinchona alkaloids, so long must this state of affairs continue, unless the varieties of cinchona which are rich in quinine can be cultivated in their natural home, South America. As DOMÍNQUEZ [6] urges, from the Argentine, this must surely be merely a matter of trial. It is now established, however, that quinine holds no antimalarial pre-eminence among the crystallisable cinchona alkaloids, and it is well known that the hardy *Cinchona succirubra*, which can be fairly widely cultivated, produces a reasonably high general alkaloidal, although a relatively low quinine content. The mixed alkaloids have been issued for many years in India and the Federated Malay States under the

name cinchona-febrifuge, and the only real difficulty in connexion with this remedy has been to devise some practical standard of purity, each batch varying in composition, and human nature being what it often is. Steps to safeguard users appear to be reaching a practical end in Malaya and Madras. They will be watched with sympathy and interest, and when this problem is solved, as surely it must be, there will be justification for cultivating the hardier cinchonas on a wide enough scale to meet the demands of our humanity.

PROBLEMS OF CEREBELLAR FUNCTION.

ONE of the topics set for discussion at the meeting last summer of the American Neurological Association and the Neurological Section of the Royal Society of Medicine was concerned with cerebellar functions, and the contributions then made by both American and English speakers have been published in a recent issue of *Brain*. Seeing that such communications have been based in some instances on original experimental work, while others can fairly be regarded as summarising what is known of the subject, and all, of course, were "up to date," the general reader may naturally and properly turn to them for the latest information on this highly controversial question. That discussions on cerebellar function have often been perversely successful in arousing controversy can scarcely be denied—a sure sign of continuing failure to solve the problem in a way commending itself to those whose opinions deserve respect. The cerebellum is a large organ anatomically, and is connected with the rest of the neuraxis by numerous tracts, entering and leaving, whose courses have been traced definitely enough. Its cortex is histologically complex yet remarkably uniform, in this respect contrasting materially with that of the cerebral hemispheres; the latter can be mapped out into 40 or 50 areas differing from each other morphologically in greater or less degree. This fact of itself can be taken justifiably to indicate relatively simple—in the sense of unitary or at least mainly undifferentiated—function for the organ. Its physiology has been studied by hosts of experimenters along the accepted lines of excitation and destruction, without, however, the attainment of finality. Stimulation of the cerebellar cortex, and of its enclosed nuclei, has in some hands resulted in the appearance of movements, on the whole of a rather tonic as opposed to phasic type. The late Sir VICTOR HORSLEY was one of those entirely convinced of the genuineness of experimental excitation of movements from the cerebellum, and at the Congress referred to above Dr. A. MUSSON substantiated the contention as the result of elaborate experiments of his own. Doubtless the matter of the interpretation of such motor phenomena requires attention. Because a given fibre-system or ganglionic collection is electrically excitable into action rendered visible by movement of the animal operated on, it does not follow this is its sole function in the intact animal; it may form but a part of its normal function, or, alternatively, it may represent only a share taken in the function of an anatomically larger and more complex system which normally acts as a whole. The method of destruction of given regions of the cerebellar cortex, or of its nuclei, or of extirpation of half or the whole of the organ, serves usefully to enable anatomical connexions to be studied by degeneration technique, but in regard to function it is essentially a negative procedure; for what the experimentalist does is in reality to study what functions are left. How unsatisfactory such a method can become scarcely needs emphasising. Thus while excitation supplies comparatively little direct evidence of cerebellar function, extirpation or destruction forms as it were an inverted approach to the problem.

Since the earlier researches of Sir CHARLES SHERRINGTON there has developed an increasing tendency on the part of some neurophysiologists to utilise spinal, decerebrate, or thalamic animals for the determination and analysis of specific functions referable to one or other part or system of such of the "preparation" as is left. That is to say, to investigate spinal functions the spinal cord is isolated; for mesencephalo-cerebello-ponto-spinal functions the animal is decerebrated, and so on. The procedure has been carried to its limits in the fine work of the late Prof. R. MAGNUS and his collaborators, and has been instrumental in enabling them to fix the functions of mechanisms concerned in equilibration and posture, and individualise the parts played by organs such as the labyrinths, otoliths, eyes, and neck in maintenance of the erect position. In some respects, nevertheless, decerebrate technique can be misleading, especially if conclusions derived therefrom are applied to intact organisms without due attention to results obtained by other methods. Up to a quite recent period cerebellar function was thought to consist largely in the regulation of muscle tonus and the coördination of (unconscious) tonic or postural motor activities. Now the decerebrate "preparation," consisting of lower midbrain, cerebellum, pons, medulla and cord exhibits in a striking form all the phenomena of reflex postural action and integrity of muscle tone as well, but a conclusion reached by several experimenters (now of an older generation) that the cerebellum is not essential for these reactions has been amply corroborated by the researches of Drs. L. J. POLLOCK and L. DAVIS, reported at the Congress. They have demonstrated that the influence of that organ on the reflex activities of the decerebrate animal is practically nil; if anything, it rather inhibits these than otherwise. These results appear to suggest that the functions just mentioned will have to be discarded from the totality ascribed to that organ. Yet in point of fact the question of their interpretation is left untouched. How far are they applicable to the intact animal, and to man?

This aspect of the general problem remains to be examined, but it cannot be said we have as yet evolved comprehensive principles for guidance. We do know that integration of diverse functions must take place constantly at different physiological levels, whatever the individual parts responsible for portions of them. The large size of the cerebellum, its prominence, its development throughout the animal kingdom, and its relative architectonic uniformity, are such as to render probable the attribution to it of an ordinary, essential, universal function, a function that neither is subtle nor requires much differentiation; and as no line of evidence, clinical or experimental, points to this belonging to the order of sensation, by exclusion and for other obvious reasons we can take it to be of the motor series. At this stage resort to the conclusions derived from the accumulation of clinico-pathological data, over a very long period indeed, justifies the assertion that a part, possibly the major part, of cerebellar activity in the normal person is concerned with the function of coördination of movement, but not with its innervation. In other words, the rôle is subsidiary to that of the cerebral cortex, so that when it is diseased substitutive action in respect of the cerebrum is to some extent realised. At the same

time, it is incomplete. The methods of the clinician lead him to argue that defect of cerebellar function is exteriorised by defect of coördination or of timing, so that while movement-innervation remains ataxia accompanies it. At present the indications are that the interrelation of cerebrum and cerebellum is more intimate, less readily severed but more revealing when this occurs, than that of cerebellum and other prespinal but postmesencephalic mechanisms. Should this view receive further support, then we may be prepared to find in cerebrum and cerebellum a physiological couple, from the standpoint of motility, concerned more with phasic than with static activity. The latter of the two will be linked more to the new than to the old motor system.

Some may be led impatiently to express dissatisfaction with present-day attainments in regard to knowledge of cerebellar function. That many obscurities remain after periodic assertions of a confident character concerning it seems regrettable. Yet the explanation is comparatively simple. The complexities of the problem have been too often neglected in the desire to obtain a cerebellar formulation of clinical worth. Progress is slow, and always outstripped by hypothesis and speculation, but abandonment of views that can no longer be sustained is in reality a sign of its existence.

THE OPTICAL PRACTITIONERS BILL.

THE Report of the Committee on the Optical Practitioners Bill, a summary of which appeared in our last issue, gives no support to the hopes of that large number of opticians who desire to obtain a definite status as State-sanctioned prescribers of spectacles. The Report fully recognises the prima facie reasonableness of their claim on the assumption that such work can be efficiently performed without the possession of a medical training. The increased demand for optical treatment has led bodies such as the Spectacle Makers Company and the British Optical Association to raise the standard of optical practice, and there is no need to question the good work done by many well-qualified opticians in this connexion. On the other hand, says the Report, it has brought into existence a considerable number of practitioners, the reality of whose qualification does not always correspond to the high-sounding titles which they assume. If so is it not right, the supporters of the Bill ask, that a State register should be set up so that those opticians who are qualified in this dubious way should be easily distinguishable by the public from well-trained men? It is important that the public should realise the grounds on which, in spite of the above considerations, the committee have decisively rejected the claim to registration as inadmissible in the interests of the public. In the first place, it would be impracticable to omit from the proposed register the names of those opticians who, though without special qualification, have been conducting bona fide sight-testing businesses for years. If a register is to be set up at all it would involve the admission of practically all existing opticians. A stronger objection to the proposal is that in many cases defective vision is merely a symptom of disease either of the eye itself or manifesting itself in the eye, and in some cases where vision may be brought up to normal there may still be evidence in the eye of disease which might pass undetected by anyone not trained in the same way as the ophthalmic surgeon is trained. The contention of the medical profession has always been that the prescription of glasses is a part of the medical treatment of the eyes, and no one should attempt to do it who has not had a complete medical training, as well as a special training in ophthalmology. The optician contends that he is trained by special courses at a "refraction hospital" to examine the fundus of the eye sufficiently to distinguish a normal from an abnormal fundus, and that all cases coming under the latter category would be referred by him to an ophthalmic surgeon. In this connexion we may remark that it is by no means so easy to distinguish a normal from an abnormal fundus as some would suppose. Opaque nerve-fibres, for instance, present such a striking picture that not even a tyro could miss it. Yet it has absolutely no pathological significance. On the other hand, slight changes at the macula are of grave importance, but may be so difficult to detect that in some cases few ophthalmic surgeons would care to pronounce an opinion as to their nature without the employment of a mydriatic. This matter of drugs is a further complication. There is a real danger in their use, a fact which is recognised by the opticians. The Spectacle Makers Company, for instance, have for many years exacted as a condition of granting their diploma an undertaking against the use of drugs in any form. Yet a considerable proportion of refraction cases are complicated by conditions of the lids calling for the use of remedies other than or in addition to suitable glasses. For purposes of refraction alone drugs are often essential, especially in the case of children. The dangers of the local use of atropine by any but skilled hands are well known.

The plea of the opticians that there are not enough ophthalmic surgeons to do the work is duly considered in the Report, the opinion being expressed that the demand will create the supply, and is, in fact, creating it. The present system, by which some 800 ophthalmic surgeons, or practitioners with a special knowledge of the eye, have undertaken to see insured patients in their consulting-rooms for a one-guinea fee, is working well as far as those societies are concerned who allow their members to have the benefit of it. Many societies, however, still refer their members to prescribing opticians, presumably in order to save the surgeon's fee. From the society's point of view this is an economy, but from the patient's point of view the economy may often be a false one. What he asks for is the best advice that he can possibly get. We know that the average hospital patient is exceedingly particular about the appearance of his or her spectacles, and is often willing to pay considerably more than a guinea for appearance alone. The same, we believe, is true of the average panel patient. If these people understand that an attempt is being made to put them off with a form of treatment which is not the best attainable they will not be satisfied. At least they should have a chance of supplementing the "optical benefit" allowed by their societies out of their own pockets if the benefit does not suffice to pay the fee. This question of fee appears to have given some trouble to the committee. The subject of clinics is hinted at in their Report, but we are by no means sure that this is a desirable way of getting over the difficulty. It is not suggested, we understand, that clinics should be established in which the surgeon's fee per patient should be less than half a guinea. If he is to do a complete refraction for this fee, together with a thorough examination of the eyes, would he not expect that premises, apparatus, lighting, and clerical assistance should be provided for him just as they are at a hospital, and, if so, how much would the saving amount to? Moreover, in our view it is essential that the principle of free choice of specialist for the patient should be maintained, and it is hard to see how any scheme of clinics could be reconciled with it. We do not say that a scheme of clinics staffed by ophthalmic specialists such as the British Medical Association has recently been discussing is to be absolutely rejected, but we believe that with the existence of ophthalmic hospitals offering free treatment for the poor on the one hand, and the guinea fee scheme for insured patients on the other, the scope of its utility must be limited.

What, then, is to become of the prescribing optician? The Report assumes that numbers of the population will resort to opticians in the future as they have done in the past, and they opine that even without a register a healthy competition between medical men and opticians may raise the standard in both classes of practice. They further suggest that these two sets of practitioners might act in collaboration in refraction work, presumably at clinics, but as long as there is rivalry between the two classes closer collaboration will be difficult than that which takes place when each has a defined task—the medical man prescribing glasses, the optician making them. The advances in the skill of the dispensing optician of late years have been marked. He is faced with such problems as the production of light lenses of a high power, the best forms of bifocal glasses, and the decentering necessary when prisms are prescribed. The amount of technical attainment which these things demand is great. There is at present no demand for the State registration of dispensing opticians, pledged not to prescribe. If it should come there would be no opposition to it on the part of the medical profession.

THE LONDON FLOODS.

HUNTING for scapegoats will not bring back to life the victims of the recent London floods, but something must be done to fix responsibility. The Government departments concerned include, it seems, the Ministries of Health and Agriculture, the Office of Works and the Board of Trade, and the public will be particularly interested to know what measure of coördination existed. Already the Thames Conservancy, which has no jurisdiction below Teddington, has officially laid the blame upon the lower river, the flood water from the upper Thames being apparently negligible. The Port of London Authority will doubtless return the compliment. These two bodies between them know what volume of water passes up and down. The Board of Trade, which issues such admirable advice as to coastal weather, is presumably aware if high seas are running at the mouth of the Thames. The river police cannot be entirely ignorant of the state of the tides. The metropolitan borough officials have means of knowing what areas lie below the threatened levels. If all these bodies agree that the recent flooding was inevitable, what measures were taken to warn and evacuate the occupiers of endangered premises? Even the Victoria Embankment is not an inviolable institution; its engineers may have thought that they built with a margin of absolute safety, yet the Thames surmounted it for a distance of over 100 yards near the Temple Station in 1921. Many buildings which have suffered were erected before the embankment was made; others—for example, the basements of the Tate Gallery—have been erected on plans submitted and passed in quite recent years. The practice of allowing human beings to sleep in underground rooms close to the river level receives striking condemnation. There will be many issues to be examined at whatever form of public inquiry is set up. Meanwhile the coroners' inquests may elicit information, and especially as to the condition of any weak spots in riverside retaining walls. Under the 1925 Act a single inquest can be held where deaths "appear to have been caused by the same accident or occurrence," although the bodies lie in different coroners' jurisdictions. This course has rightly not been taken in respect of the victims of the flood; each locality ought to have the fullest opportunity of producing its own evidence before its own tribunal, which best knows the local conditions.

ROYAL MICROSCOPICAL SOCIETY.—The annual meeting of this society will be held on Wednesday, Jan. 18th, at 7.45 P.M., at 20, Hanover-square, London, W. 1. At 8 P.M. Dr. James A. Murray, F.R.S., will deliver the Presidential Address on Staining and Structure.

Annotations.

"Ne quid nimis."

THE FATE OF MENTALLY DEFECTIVE CHILDREN.

DURING the last quarter of a century over 4000 Birmingham children have been pupils at special schools for mental defectives, and a remarkable survey of their after-history has now been issued.[1] Of 4052 whose career was investigated, 239 are dead; 564 have been lost sight of; 1618 are doing remunerative work, their average wage being 25*s.* 6*d* a week; 18 are soldiers; 174 were transferred to ordinary elementary schools; 34 were transferred to other schools, mainly industrial or schools for the deaf; 405 are at institutions for the mentally defective, including 36 in asylums; 156 are in other institutions, chiefly those of the poor-law; 269 were dismissed from their special schools on account of physical or mental disability; 536 are at home and said to be useful there; and 39 are at home and said to be useless. Excluding those who died or are untraced, these children may be tentatively assigned to three main groups:—

1. Those who seem to be socially efficient and self-supporting to a reasonable degree. Among these may be placed the 1618 paid workers and the 18 soldiers. It also seems reasonable to include the 174 children transferred to elementary schools, together with some—say 20—of those who were sent on to other special schools, and perhaps half of the 536 who are described as "useful at home." This makes a total of 2098.

2. Those suited for institutional care, including the 405 in institutions for mental defectives, the 156 in other institutions, the 269 dismissed as incapable from special schools, and the 39 useless at home. In this group the total would be 869.

3. Those that might be left at home under supervision, although socially inefficient. This would include the remaining half of those who are "useful at home" and the remaining 14 of those transferred to special schools, and gives a total of 282.

Thus of the 3249 cases definitely ascertained 2098 (64 per cent.) are presumably satisfactory; 869 (26 per cent.) are only suitable for institutional care; and 282 (9 per cent.) belong to the intermediate class and might remain at home under supervision. These figures reflect credit on the training provided in these special schools and on the measures of after-care.

The above grouping is not suggested by the Birmingham After-care Subcommittee and some comments and qualifications are necessary. Of the 1618 children doing remunerative work a few are earning wages that would not by any means support them, and it is surprising to find that only 12 are engaged in bootwork and 14 in woodwork which are the main handicrafts taught in the special schools. The better children, it appears, are allowed to leave at the age of 14, and probably the results would be more satisfactory if the later years were devoted to elementary vocational training. In Group 2 there are 156 persons in institutions other than those for the mentally defective, besides 36 in asylums; it would be decidedly better if all these defectives were in the institutions provided specially for them. As regards Group 3 it would be an advantage if as many as possible of the defectives living at home could attend occupation centres; at present the number who do so is only 35. It would, of course, involve some trouble and expenditure on the establishment of more centres and the provision of guides, but (as the report states) "the benefits to the child and the home are very great, and the centres provide excellent means of supervision and elementary training for certain children who would otherwise need institutional care."

The after-history of the defectives themselves is not the only thing that has been studied, and the report

[1] Report of the Birmingham After-care Subcommittee, issued from the Offices of the Education Committee, Birmingham.

contains notes on the condition of 156 children, of 5 years and upwards, born to parents one of whom is mentally defective. In this series 146 appear to be normal, 7 are in schools or colonies for the mentally defective, and 3 are in some other way abnormal. Thus at least 7 out of 156 (nearly 4½ per cent.) are mentally defective, and probably this figure should be higher—i.e., in greater excess of the 1 per cent. that might be expected from normal parentage. The numbers are small and not all the children have reached the age when ascertainment is compulsory or indeed can be depended upon. The Committee makes the tentative suggestion that when the father is the defective most of the children are female, and vice versa; but in the groups given the sex of the children is not always stated. The further suggestion that the deficiency of the parent emerges more on the opposite sex also remains to be proved. In the meantime investigations of this kind are of great interest.

PULSE-WAVE VELOCITY.

IMPAIRMENT of arterial elasticity has long been recognised as playing an important part in the production of circulatory insufficiency, but no satisfactory clinical method has been introduced for accurate quantitative measurement of the impairment in particular cases. Palpation of the superficial vessels, or inspection of the retinal arteries with the ophthalmoscope, will generally reveal advanced structural changes; but this information is merely qualitative. For a quantitative estimate of arterial elasticity one must have recourse to an indirect method, based on observations of the velocity of transmission of the pulse-wave; and before the results can be applied to the study of disease, it is necessary to determine the limits of accuracy of these observations and the range of normal variation. This has been attempted recently by Dr. Otto Beyerholm.[1] He found that the average pulse-wave velocity in persons between the ages of 15 and 60 was just over 7 metres per second, readings above 8 or below 6 metres being exceptional. Amongst children and older people the number of observations was too small to yield reliable figures, though a general tendency of pulse-wave velocity to vary with age was noted. He points out that even in a uniform sample of material, composed of subjects of the same age and sex, individual readings may vary by as much as 2 metres per second, whereas readings differing by more than 1 metre may be obtained from the same subject at different times. These values are very similar to those previously recorded by Bramwell, Hill and McSwiney.[2] They and their collaborators made a further series of observations on the relation of arterial elasticity to diastolic blood pressure, both in excised human arteries and in the living subject, and their conclusions may be summarised by saying that the extensibility of the arterial wall depends on two factors—(1) the structure of the vessel, and (2) the diastolic blood pressure. Even in the absence of any morbid changes in the vessel wall a high diastolic pressure may be instrumental in producing impairment of the functional efficiency of the arteries, which can be recognised by an unduly high reading of pulse-wave velocity.

In considering the clinical value of pulse-wave velocity as an index of arterial insufficiency, there are various points which have to be taken into account. In the first place, in the investigations mentioned, only one particular segment of the arterial system has been considered, and it may not be justifiable to regard the arteries of the upper limb as a fair sample. How far do pathological changes in this situation imply similar changes in other parts of the body? Disease affecting the limb arteries would be relatively unimportant provided the cerebral and coronary arteries were healthy. Again, the readings obtained give only the mean velocity in the vessels of the upper limb, whereas stiffening of the aorta and its great elastic branches may lead to very different results from similar changes affecting the smaller and more muscular arteries. Lastly, in any test of functional efficiency it is necessary to consider the degree of impairment which may exist without becoming manifest. It is well known, for example, that the slighter degrees of renal insufficiency are not associated with any rise in the blood-urea, and in the same way it is necessary to ascertain to what extent the arterial walls may lose their elasticity without producing a rise in pulse-wave velocity sufficient to be recognised as pathological. Further investigations are needed in order to answer these questions, and to render available for clinical purposes a test which promises to be useful in diagnosis.

ANTENATAL WORK AT A SCOTTISH MATERNITY.

THE medical report of the Glasgow Royal Maternity and Women's Hospital for the year 1926 is arranged in accordance with the standard scheme for unification of maternity hospital reports, suggested by a committee of the Royal Society of Medicine. The intrinsic value of this report is evident seeing that the hospital deals annually with nearly 8000 patients, not including the antenatal and postnatal dispensaries. Its value is further increased by the comparison of the results of treatment in the case of patients who have received antenatal care, of those who have had no antenatal examination, and of the frank emergencies. Information on these lines is difficult to obtain, and is much needed at the present time, when the extension of antenatal treatment depends so largely on a recognition of its value.

The report opens with a numerical summary of presentations. There were 42 breech and transverse presentations among 1387 cases (2·4 per cent.) which had had antenatal care and 21 among 538 cases (3·9 per cent.) which had not. It is apparent from these figures that version had been performed on a considerable number of breech presentations in the antenatal department; the tables of maternal and fœtal mortalities given on pages 16–17 justify an extension of this procedure, for a maternal mortality of 3·6 per cent., and a fœtal mortality of 27 per cent., are above the average mortality-rates for this presentation. Pelvic contraction was treated by induction of labour in three cases, by Cæsarean section in 108, and by craniotomy in 19. Of cases under antenatal supervision labour was induced in eight such cases (there is a discrepancy in these figures referred to in the report), Cæsarean section performed in 74, and craniotomy in five. The fœtal mortality in 83 cases of spontaneous labour was 7·2 per cent. These figures clearly contrast the treatment of pelvic contraction in Glasgow and London. The most interesting tables in the report are those dealing with the treatment of antepartum hæmorrhage. Taking the 86 cases of placenta prævia, there was no maternal death and a 50 per cent. fœtal death-rate among 11 antenatal cases, contrasting with the emergency cases (66 cases) in which the maternal mortality was 9 per cent. and the fœtal 87 per cent. These figures well illustrate the value of antenatal work even in such a condition as unavoidable hæmorrhage; but they still contrast with those of accidental hæmorrhage in which the maternal death-rate was only 1·7 per cent. and the fœtal 50 per cent. Conservative treatment was the method of election, Cæsarean section being rarely performed for antepartum hæmorrhage. The report deals fully with toxæmic pregnancy. The maternal mortality in 72 cases of eclampsia was 15 per cent., about one-quarter lower than the average figure for all hospitals, and again Cæsarean section was the exception. The fœtal mortality-rate is not given though the information is available for calculating it. The morbidity-rate (B.M.A. standard) for the whole hospital is 10·6 per cent., for the emergency cases 13·9 per cent., and for

the antenatal cases only 8·6 per cent., further evidence of the value of antenatal work, although the figures are a little higher than might have been anticipated. The summary of fatal cases includes five of rupture of the uterus, three of which died of peritonitis, and two apparently of shock; there is no record of recovery from this accident.

Hospital reports if properly compiled have real value to those engaged in similar work. This report has been carefully put together and is a credit to the registrar.

EDUCATION OF THE DEAF.

AN address was recently delivered by Mr. Sibley Haycock, superintendent of the Langside School for the Deaf, Glasgow, to the Scoto-Irish Branch of the National College of Teachers of the Deaf, Dumb, and Blind, Belfast, and his words contained information of particular interest to the medical profession. To all of us it is perfectly well known that our large deaf population is practically wasted for civic and social purposes almost solely because of want of education. The majority of these people are quite able to discharge competently most of the duties of a citizen, and this would become obvious at once to the public if the barrier which their defect erects between them and the hearing population were not so lamentably maintained. There are only 16 residential schools for deaf children in this country and Scotland, and only 450 qualified teachers, all of whom are still badly paid, though this position is at last receiving attention, Government recognition having brought with it financial aid. The services of Dr. Eichholz, chief of the medical department of the Board of Education, have been immensely valuable in the attempts of what is still a small body of enthusiasts to meet the situation, for his general understanding of the capacities of the deaf child, gained by personal inspection of all kinds of schools, has helped to a better understanding of the problems before us. Mr. Haycock, in his address, set out many of these things in detail, concluding with a practical explanation of the special nature of the work of teachers of the deaf. Here he laid stress on the fact that the psychology to be dealt with is that of the normal child, but normal only up to a certain point, as so much of the instruction that is gained by hearing is lost to the deaf subject in his silent world. The deprivation of mental reactions must retard the development of the deaf-born child unless real communication is quickly established between him and the hearing world. The only way in which this connexion can be brought about is through lip-reading, and the elaborate course of instruction required should commence in babyhood. Mr. Haycock says: "If a deaf child is to be given the best chance of having the severe handicap of his deafness minimised to the fullest possible extent; that is, if he is to have the best chance of learning to speak and of understanding the speeches of others, his education, of necessity, must start early, and, school conditions being satisfactory, the earlier the better." There must be common agreement with this statement, which forms a serious reflection upon us all when we remember how small is the effort as yet to supply the special teaching required, and when we hesitate to say that this teaching is as thorough as it has been in the past.

EXPERIMENTS WITH B.C.G.

SOME time ago Calmette suggested that immunity against tuberculosis might be developed by the introduction into the body of living tubercle bacilli which had been rendered avirulent by prolonged growth under abnormal conditions. This suggestion is academically irreproachable and conforms to the traditional Pasteurian method of vaccination. The strain of tubercle bacilli which he produced is known, in current laboratory slang, as B.C.G. (Bilié-Calmette-Guérin). Its use is avowedly not without risks, and Calmette proposed that it should be employed primarily for the protection of infants whose parents had active tuberculosis and whose expectation of life would ordinarily be bad. Basing his technique on a belief in the overwhelming importance of the alimentary tract as the initial port of entry of the tubercle bacillus, he has treated many such children with oral doses of the vaccine, and claims that the results are excellent. He considers that the bacilli, although no longer virulent, largely retain their antigenic powers, and therefore evoke antituberculous immunity. This opinion is supported by some experiments on guinea-pigs recently reported[1] by Japanese investigators. In the first experiment a number of the animals were given an intravenous injection of B.C.G., and were later tested for their reaction to tuberculin as well as their response to subsequent inoculations with virulent tubercle bacilli. Both tests indicated that a certain degree of immunity was definitely established, and although in these inoculated animals infection could still be induced with large doses, it progressed more slowly in them, and with a greater tendency to heal, than it did in control animals. The second series of experiments more closely reproduced the clinical circumstances envisaged by Calmette. Guinea-pigs were given intragastric doses of the vaccine preparation, and a month later these were followed by a known effective dose of bacilli of a virulent strain. In untreated animals the effect of the virulent organisms was to produce a tuberculosis of the abdominal glands, most pronounced, at the time of examination, in those of the subpyloric group. In the vast majority of the treated animals, examination three weeks after the virulent organisms had been ingested revealed no enlargement or other alteration of these glands; in a few cases an enlargement described as "inflammatory" in nature was noted; only very exceptionally were any changes found suggestive of actual tuberculosis. The sum of these experiments is to support the thesis that a definite immunity can be produced by B.C.G. It would be useful to have further information about the possibility of lesions developing at a later stage than the period which they cover and about the effect of the treatment on the ultimate survival of the animals.

A review of Prof. Calmette's new book on preventive vaccination with B.C.G. will be found on p. 84 of our present issue.

MENSTRUATION AND THYROID FUNCTION.

THE close relationship between thyroid and ovarian function has long been recognised, but the laws governing it are still obscure. In this field, as in many others, little is gained by studying the normal; enlightenment is more likely to come from observing the reproductive abnormalities of patients suffering from thyroid disease. The evidence yielded by such observations has been valuable but hard to comprehend. Exophthalmic goitre, for instance, may be associated with either amenorrhœa or menorrhagia—an apparent contradiction also seen in myxœdema, which stands at the opposite end of the scale of thyroid disorder. As a result of their investigations of 300 cases of thyroid disease,[2] Dr. H. Gardiner-Hill and Dr. J. Forest Smith deduce two principles: (1) that when menstruation is affected by a given thyroid fault the alteration tends to be in a uniform direction; and (2) that the weaker the thyroid the greater the flow. The series included nine cretins, 100 cases of adolescent goitre with varying degrees of thyroid disturbance, 96 of exophthalmic goitre and hyperthyroidism, 41 of myxœdema, 24 of parenchymatous goitre, and 22 of simple adenoma of the thyroid. The cretins' behaviour confirmed the findings of previous authorities;

[1] Annales de l'Institut Pasteur, 1927, vol. xli. Essais d'immunisation avec le B.C.G. Calmette Guérin, by Prof. M. D. Arao Imamura and Dr. Michihiko Takashashi.—Sur l'immunité des cobayes vis-à-vis de l'infection entérale par le bacille tuberculeux humain après, administration intragastrique de B.C.G. Calmette Guérin, by Dr. Kiyoshi Satake.

[2] Jour. Obst. and Gyn., 1927, xxxiv., 701.

menstruation was very late in spite of thyroid medication, but once started was normal and regular. Of the adolescent goitres 79 per cent. seemed to be of the colloid variety, with varying degrees of thyroid function, and 16 per cent. were ordinary cases of exophthalmic goitre. The basal metabolic rate was over +10 per cent. in all the latter, and in general the B.M.R. figures agreed very closely with the clinical grouping. In 63 per cent., however, of those colloid goitres in which hypofunction was diagnosed clinically, the B.M.R. was more or less normal, a fact which provides interesting confirmation of the view that many such goitres are compensatory enlargements. Menstruation was regular and normal in about half the patients with colloid goitre, whatever the state of the thyroid, and in most of tne remainder it varied inversely with the thyroid's activity, amenorrhœa being associated with hyperthyroidism and menorrhagia with hypothyroidism. The exophthalmic patients with their high B.M.R. mostly complained of amenorrhœa.

The group of adult exophthalmic and hyperthyroid patients gave similar results; 57 per cent. of those with definite primary Graves's disease had delayed or irregular periods, whilst 42 per cent. menstruated normally. Of those with less thyroid enlargement and no definite ocular signs only 27 per cent. had scanty menstruation, whilst 65 per cent. were normal. A section of this work suggests an interesting explanation of the apparent anomaly of amenorrhœa and menorrhagia both being reported as symptoms of myxœdema. Dr. Gardiner-Hill and Dr. Forest Smith notice that when myxœdema develops before the menopause it is often accompanied by menorrhagia, and rarely by amenorrhœa. In several of their cases, however, it was preceded by a natural menopause, and they suggest that this kind of occurrence accounts for the impression that myxœdema causes amenorrhœa. The effect of the disease on the œstral functions can only be estimated, they consider, by taking into account whether it occurs before a natural menopause, after a natural menopause, or after a premature one. If before the menopause they find that the usual reaction is menorrhagia; two-thirds of their patients fall into this group. In the remaining third menstruation had been regular until the menopause, and myxœdema had developed a considerable time after it. Three patients who had had a premature menopause showed signs of the disease so long afterwards as to make it very unlikely that the cessation of menstruation was due to the thyroid disturbance.

Of the patients with parenchymatous goitre, 79 per cent. had normal and regular periods and the remainder tended to menorrhagia; none had amenorrhœa. In the large majority, however, there was no gross disturbance of thyroid function. Similarly, 83 per cent. of patients with adenomata of the thyroid menstruated regularly, and the remainder were divided between amenorrhœa and menorrhagia. The few patients in both groups whose thyroid activity was subnormal suffered from menorrhagia. This is consistent with the two general conclusions which Dr. Gardiner-Hill and Dr. Forest Smith have drawn, and their conclusions will undoubtedly be of great assistance in the explanation of menstrual abnormalities in which there has hitherto seemed to be neither rhyme nor reason.

THE CORRELATION OF PHYSICAL AND MENTAL EXCELLENCE.

THE adage about sane minds and healthy bodies is more often quoted as an exhortation than a statement of fact, but a series of investigations carried out at the Manchester Grammar School by Dr. A. A. Mumford go far to show that it is indeed true that the successful scholar is in most cases the successful athlete, or, at least, the owner of a well-developed body. Dr. Mumford, it seems, is ready to glean in any field for straws which will show the way of the wind, and he has made use of such diverse sources of information as Sir Arthur Keith's "Mechanism of Respiration in Man," the aphorisms of a tailor's cutter, and the measurements of mediæval brasses and suits of armour. The tables finally produced are a modification of those devised by Mr. Cecil Hawkins in 1905, a functional element being introduced by adding the tests for air-pilots constructed by Group-Captain Martin Flack, of the Royal Air Force Medical Service.

At Manchester Grammar School Dr. Mumford has arranged that every boy's record card should have space for annual measurements of height, weight, and the girth of the chest and upper and lower arm, together with general estimates of work and character by the high master and of health by the medical officer, and statements on place in class, method, and time spent on travel, and other points seeming to be relevant. The boys were watched in gymnasium, swimming-bath, and playing-fields, and every effort was made to ascertain individual needs and capacities. Describing his conclusions recently to the Royal Anthropological Institute Dr. Mumford showed how his careful study had confirmed many "common-sense" opinions. The words "physical fitness," he maintains, nowadays have the same kind of soporific effect on human judgment as the term "salvation" had a hundred years ago. As a certificate of security fitness is valueless unless some definite object is in view. A school medical officer must not only study and measure the physical capacity of his pupils; he must also study their adaptability and their preparedness for a wider and equally strenuous future, when they will be under no watchful supervision. It is possible, Dr. Mumford claims, to predict from the shape and movements of the chest of a boy of 12 the directions in which he is most likely to be successful, and to advise the particular form of exercise calculated to make good his deficiencies. The swimmer, the boxer, the long-distance runner, and the student each have their own way of breathing, which can be recorded on a drum. Physical measurements, he considers, are related to mental activity and to the capacity to withstand and recover from mental strain in school life. "Without properly conducted and periodically reviewed systematic measurements of physical and mental growth considered in relation to one another," he says, "it is impossible to judge the effect of mental concentration either on the boy's present growth or his future fitness for civic life. Classwork in school calls for activity of the same bodily organs and to some extent the same tissues as does physical exercise, though in a different way and to a different degree." To confirm this belief in the inter-relation of the two elements he studied a series of 285 boys who had gained entrance scholarships at Oxford or Cambridge during the last 20 years. These boys were found to display a somewhat accelerated physical growth when compared with the average, and they had a slightly better physical frame and fuller breathing capacity. The greater acceleration in growth of chest-girth was more marked among those who took first-class honours at the University than among the seconds and thirds. There was evidence that men in the latter groups used up in study some of the energy which might otherwise have been available for physical development. The average chance of exhibiting physical excellence at school—by gaining school colours and sports awards—was one in ten, but one in every three of the scholarship boys had secured some mark of prowess. Moreover, the greater the degree of mental excellence the greater was the physical excellence. One boy in four in the first-class group, one boy in five in the second-class group, and one boy in nine in the third-class group had been awarded colours. Dr. Mumford's conclusion is that the study of the adaptability of the human frame to meet the demands of the various forms of mental and bodily work required in modern civilisation should be one of the principal objects of the modern school medical officer.

A SWISS TOUR.

PROFIT and pleasure were happily blended in the visit paid to sanatoria and other institutions in Switzerland during the last fortnight of the year by a party of medical men and women, some 70 in number, who took the opportunity of arrangements made by the Council of the Royal Institute of Public Health with the coöperation of Sir Henry Lunn. The first halt occurred at Zurich, where an instructive visit was paid to Dr. R. Scherb's orthopædic clinic known as Balgrist. Here there are 140 beds for the treatment and functional re-education of children with dystrophies and deformities of all kinds, and a special ward devoted to poliomyelitis demonstrates the possibility of muscular recovery even after the expiry of a year from the primary infection. Dr. Scherb gave a convincing demonstration of the fact that physiological movements alone do not avail to cure the deformity of established scoliosis. As is usual in Switzerland a large proportion of the operations are done under local anæsthesia, a method of particular utility to the orthopædic surgeon who has to make the most of what muscular and nervous mechanism is available. Attached to the clinic is a school with primary, secondary, and infant departments under municipal control, and a technical section in which various trades are taught to the older patients in collaboration with local trade-unions. A visit was also paid to the Zurich skin hospital which rejoices in an almost complete collection of life-sized coloured wax models of skin lesions. Having reached the Grisons the party went straight up the admirable electric railway, claimed to be the steepest adhesion line in the world, to Arosa where Dr. Amrein showed them the lavish equipment of the Altein Sanatorium. Davos, with its many public utility services, was the next objective, beginning with the controlled dairy where elaborate precautions are taken to ensure the purity of the milk and the institution which formerly bore the name of Queen Alexandra, but has now become a popular sanatorium for the Canton of Thurgau. In the evening a reception was given to the visitors by the Davos Medical Society, over which Dr. Biland presides. The party was put in touch with the extensive research on climate in relation to human physiology which is being carried out in the valley under the (temporary) direction of Dr. Lindholm, official meteorologist to the Swedish Government. A clinical lecture given in Davos is reported on another page. Proceeding along the Albula railway to the Engadine, the visitors were received at St. Moritz by Dr. Bernhard, the pioneer of sunlight treatment, and were then driven past the frozen lakes to Maloja at the head of the valley, where the week-end was frankly spent in the pursuit of winter sport. The convenient route to Western Switzerland was then taken, down the Bergell and via Milan and the Simplon tunnel to Sierre, from which Montana was reached by the two-stage funicular railway, and the party was entertained at the Palace Sanatorium, now the only English sanatorium in Switzerland for pulmonary cases. Here Dr. A. J. Morland gave them some account of his clinical experience with sanocrysin. Later they were shown over the newly-built Moubra Sanatorium, planned by M. Heer on the latest and most approved lines for the treatment of surgical tuberculosis. Patients at the Palace Sanatorium who require such surgical treatment as phrenic exairesis or thoracoplasty are transferred temporarily to Moubra for this purpose. The last objective of the tour was Leysin where Dr. Rollier entertained the party with a lantern lecture on the therapeutic and social value of heliotherapy, and an admirable demonstration followed of the technique of treatment and of the various forms of occupational therapy, ending with a film exhibiting the "school in the sun" with a demonstration of some actual classes. A special train conveyed the visitors to the graded institutions of the Société Climatérique, including the Sanatorium Grand-Hotel under Dr. Jaquerod. The organisation and planning of the tour left nothing to be desired, and the party returned with pleasant memories of the hospitality received.

ALCOHOL AND THE HUMAN BODY.

TRADITION and enthusiasm have surrounded the whole subject of the action of alcohol with a mist of fiction. It is interesting, therefore, for the general observer to hear an impartial summary of the present scientific position from so wise an authority as Prof. Hugh MacLean, of St. Thomas's Hospital. In a paper on Alcohol and Alcoholism in relation to Problems of Nutrition and Health, read before the Society for the Study of Inebriety, on Tuesday last, Jan. 10th, Prof. MacLean put first the question: Is alcohol a food? Even this, he said, cannot yet be answered with absolute certainty, in spite of a great deal of experimental work. A foodstuff may be defined as fuel that can be used by the body as a source of energy. Protein alone can help to repair the animal organism; fats and carbohydrates can only supply energy. Alcohol, therefore, lacking the essential nitrogenous element of a protein, can never repair tissue waste. As a source of fuel-supply, alcohol will give seven calories for every gramme oxidised, whereas starch will give four calories and fat nine calories. Unlike other foodstuffs, alcohol requires no digestion, and 50 per cent. of it is absorbed directly from the stomach, whence it is very rapidly and evenly distributed over all the soft tissues, even penetrating the bones to some extent. Only 5 per cent. of a moderate dose is excreted by the usual channels, 95 per cent. disappearing by oxidation in the body. The work of Atwater and Benedict in America showed that alcohol is rather more efficiently oxidised than ordinary foodstuffs, that it can replace fat, starch or protein as a source of energy, and that, after a small temporary loss, the body protein is spared. When the amount of work to be undertaken is small, alcohol appears to be just as good as other forms of food, but it fails when a heavy task lies before the body or when a high degree of discrimination or correlation is demanded. There is some evidence, said Prof. MacLean, that the mechanism of the muscles for oxidising alcohol is different from that for oxidising fat and sugar, for in some conditions the latter may be lost and the former retained. In diabetes, a disease which he has studied closely, the patient can sometimes obtain nourishment, within limits, from alcohol when fat and sugar fail him. The idea that more work can be done if alcohol is taken in addition to a normal diet is beloved of the working man, but Prof. MacLean declared it to be a myth. Nevertheless, reviewing the experimental evidence, he concluded that alcohol is a food, but that there is no reason why it should be substituted for ordinary food under ordinary conditions of health. In disease, however, a patient may be unable to take or to digest ordinary food, but may be able to obtain for a short time from alcohol sufficient calories to keep him alive. The body can oxidise 8 c.cm. of alcohol in an hour, therefore under exceptional circumstances the administration of eight ounces of brandy in the day may produce 700 or more calories, and make all the difference between life and death. The undoubted stimulation of the ferment-producing power of the stomach made alcohol, in his opinion, a useful addition to the diet of elderly people and others in whom the secretion is feeble, and the psychological effect may make all the difference between distaste for and good digestion of a meal. Apart from this, however, the continued secretion of gastric juice after the stomach was empty could only be harmful, particularly in ulceration or sthenic dyspepsias. On the intestines, said Prof. MacLean, alcohol has no action, nor does a moderate amount affect the kidneys; its supposed action as a cardiac stimulant is entirely due to indirect action, probably on the mucosæ of the tongue and stomach. On the

liver falls the brunt of absorption, and therefore of chronic alcoholism, and it is the liver that prescribers of alcohol must remember when they consider its dangers. Dr. Alex. Cawadias, in the subsequent discussion, described experiments of his own which had impressed on him the selective action of alcohol on the liver and the peculiar sensitiveness of this organ to the drug. Alcohol is a food, he said, but at the same time it destroys the gland that metabolises food, and disturbs the metabolism of proteins. This incomplete metabolism of proteins, according to Dr. Cawadias, is the cause of many allergic symptoms, vague nutritional disturbances often classed as "neuroses." Prof. MacLean believed that alcohol contributes to fatty degeneration, and Sir William Willcox described the rare acute case which was so sudden and so severe as to be taken for arsenical poisoning. In moderate regular drinkers, too, glycosuria is not uncommon, and ceases as soon as the consumption of alcohol is reduced.

THE British Empire Cancer Campaign is arranging an International Convention on Cancer Research to be held in London next July. Sir John Bland-Sutton, who is the vice-chairman of the Campaign, will preside over the Convention, and sections will be devoted to Pathology, Diagnosis, Medical Treatment, Surgical Treatment, Radiological Treatment, and Public Health and Statistics. The following have been appointed chairmen of sections: Pathology, Prof. W. S. Lazarus-Barlow; Diagnosis, Sir Thomas Horder; Surgical Treatment, Sir Charles Gordon-Watson; Radiological Treatment, Prof. Sidney Russ, D.Sc.; Public Health and Statistics, Dr. F. E. Fremantle, M.P. Sir William Willcox and Dr. Robert Knox will act as vice-chairmen of the Section of Diagnosis and Radiological Treatment respectively. Invitations are being sent, it is stated, to authorities on cancer all over the world, and the universities and medical schools of the United Kingdom will be invited to send delegates. Sir Richard Garton, chairman of the Finance Committee of the British Empire Cancer Campaign, is making a donation towards the expenses of the Convention, and it is intended that no part of the Campaign's funds shall be used to defray them. The Royal Society of Medicine has offered its premises for the meetings, and the Duke and Duchess of York will attend a soirée at which delegates will be received. The chairman of the Convention Committee is Mr. J. P. Lockhart-Mummery.

Sir Thomas Horder has been invited to become a Freeman of Shaftesbury, which is his native town.

INDEX TO "THE LANCET," VOL. II., 1927.

THE Index and Title-page to Vol. II., 1927, which was completed with the issue of Dec. 31st, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

INTERNATIONAL BULLETIN OF MILITARY MEDICINE AND PHARMACY.—At the Fourth International Congress on Military Medicine and Pharmacy held at Warsaw last year, at which 36 delegations from foreign countries were present and over 2000 individual members, it was decided that a permanent link should be established between the medico-military organisations of the different countries by the publication of an International Bulletin. This Bulletin is to appear monthly from Jan. 1st, through the medium of the *Archives Médicales Belges*, and for the moment will only be published in French and English. It will consist of articles of a technical character furnished by the national delegations of each country who will send their work, with the approval of the health services of their respective countries, to the editorial committee of the Bulletin, a body which is appointed by the Permanent Committee of the Congress on which the national delegations are represented. The editor is the secretary of the Permanent Committee, Dr. Voncken, Hôpital Militaire de Liége, Belgium, from whom particulars may be obtained.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLVIII.

THE TREATMENT OF TUBERCULOUS EPIDIDYMITIS.

BEFORE considering the treatment of tuberculosis as it affects the testicular apparatus it is essential to appreciate the cardinal features of its onset and course. The age-incidence is from puberty onwards; tuberculosis of the testis is unknown in childhood, apart from generalised miliary tuberculosis, and the majority of cases occur between the ages of 25 and 45, after which time the condition becomes progressively less common. This accords with the period of fullest activity in the testis. It is agreed that the disease attacks the epididymis first, the body of the testis if involved being affected secondarily. Any gross degree of hydrocele is therefore unusual, though a small amount of fluid in the tunica is a common feature. There is general consensus of opinion that the part of the epididymis attacked first as a rule is the globus minor, and the earliest clinical sign is a nodule in this situation. If the disease spreads unchecked the nodule will enlarge, and tend to soften and caseate, becoming adherent to the skin and forming a sinus on the postero-lateral aspect of the scrotum. The rest of the epididymis becomes involved with secondary caseating foci. The testis is destroyed by caseation and fibrosis, but the process being slow testicular sensation remains unaffected for a long time. The vas deferens exhibits nodular thickening, and rectal examination reveals thickening and softening in the vesiculæ seminales or prostate. Later the testis of the opposite side becomes affected, and the bladder may be the seat of tuberculous cystitis. The kidney also may show evidence of infection.

Differential Diagnosis.

Differentiation from such conditions as syphilis or neoplasm of the testis or the acute infections of the testicular apparatus should offer little difficulty. There are, however, certain conditions which give rise to fibrous thickening in the epididymis which must be borne in mind. Fibrosis may follow previous inflammation due to the gonococcus or *Bacillus coli* or damage produced by vascular interference through partial torsion of, or thrombosis in, the spermatic cord. A careful consideration of the history, combined with rectal examination and possibly prostatic massage and urethroscopy, should clear up the diagnosis.

Healing without Operative Interference.

What has been described is the extreme picture of progressive disease; the rate of spread, like that of tuberculosis elsewhere in the body, is, in fact, extremely variable. Thus a nodule may remain indolent in the globus minor for a number of years or breaking down may form a sinus, only to heal up again after discharging for a time. This last is important, as it is not recognised clearly that healing by fibrosis will occur in this particular situation. Although occasionally the whole process is a rapid one, so that an acute form of the disease may be described, the average duration of symptoms before relief is sought is nine months. Quite half the cases exhibit discharging sinuses when they are first seen. The inference to be drawn from the above facts is that, given a high enough resistance on the part of the patient to the tubercle bacillus, and the means of augmenting this are well known, the disease, like tuberculous inflammation occurring elsewhere in the body, has a tendency to natural arrest through healing by fibrosis. This healing process is encouraged by local rest.

Medical treatment, or rather the withholding of surgical treatment, is indicated when a firm nodule in the epididymis is the only evidence of disease. If at any time softening or spread in the epididymis

commence, surgical treatment, as detailed below, is required. In certain of these cases presenting merely a nodule in the epididymis, in spite of the most complete investigation, it is obvious from what has been said above the diagnosis must remain in doubt.

To the surgeon, at any rate, the eradication of the primary focus of the disease in the urogenital tract would seem to be a more rapid and certain procedure. Unfortunately, however, we are still ignorant of the exact site of primary infection in the genito-urinary system. The epididymis may be the primary site, being attacked via the blood stream, or it may be infected via the vas from a primary focus in the prostate or vesicle, as in the commoner disease of gonorrhœal epididymitis. In substantiation of the latter view is the fact that many cases exhibiting early and trivial signs in the epididymis show marked involvement of the vesicle and prostate, and that in many cases of very early and radical removal of the testis, epididymis and vas involvement of the opposite epididymis nevertheless occurs. H. H. Young, in a series of 222 cases of genital tuberculosis, found that in 47 cases the prostate and vesicle were infected by tuberculosis without any lesion in the epididymis. Moreover, the focus is found first in the globus minor or prostatic end of the epididymis, whereas the frankly blood-borne infections of the testicular apparatus, such as mumps and gout, attack the body of the testis primarily.

Surgical Measures.

The forms of surgical treatment appropriate for different types of case include (1) incision and curetting, (2) epididymectomy, (3) orchidectomy, (4) radical removal of the seminal tract.

Incision and curetting.—This may be utilised as a temporary measure where a caseating focus in the scrotum is on the point of ulcerating through the skin. As a rule it will be followed by more radical treatment, although in cases where there is extensive tuberculosis of other organs, such as the lung, it may be injudicious to undertake any further surgical interference.

Epididymectomy.—This operation can be undertaken without fear of endangering the blood-supply of the testis, and should be carried out where the disease has not yet involved this organ. The lower third of the vas deferens should be removed at the same time. Obviously this would be the operation of choice if the epididymis were known to be the primary focus in the genito-urinary tract, but it may be asked whether it has any value if the vesicle and prostate are affected. Even where these organs are involved, primarily or secondarily, however, it is clear that by removing part of the infected tissue, particularly if it happen to be the major part, the recuperative powers of the body are given a better prospect of overcoming the infection. In practice, a vesicular or prostatic lesion often clears up or ameliorates after epididymectomy. Similarly, in the operative removal of a tuberculous joint it is unlikely that all tuberculous tissue is removed, but the results of excision in suitable cases are well known.

Orchidectomy.—This should be reserved strictly for those cases in which the body of the testis is obviously affected. Apart from this it is unjustifiable. A high percentage of cases, in spite of all treatment, sooner or later attack the epididymis on both sides, and to remove the internal secretion of both testis unnecessarily in a man at the prime of life is manifestly unsound practice, and may have serious effects on the mental and general physical health of the patient.

Radical removal of the seminal tract.—This is an extensive and formidable operation. As advocated by Young, it is carried out through a perineal incision. The seminal vesicles and ampullæ are isolated, and the prostate, if infected, is removed also. The epididymes are then exposed in the scrotum, with the patient in the dorsal position, and removed together with the whole remaining portions of the vasa. The risks of the operation consist in the difficulty in dealing with the base of the bladder and the fear of a perineal urinary fistula. The peritoneum and rectum may be damaged, and, finally, the majority of the patients are not good subjects for extensive major surgery. Many exhibit active tuberculosis elsewhere, especially in the lung.

A less drastic operation may be carried out entirely through an inguinal incision, stripping back the peritoneum from the bladder until the vesicles and prostate are reached. However, if complete extirpation of the seminal tract, rather than removal of grossly infected material, is aimed at, the perineal approach to the vesicles must be adopted.

Conclusion.

Treatment should consist as a rule in removal of the epididymis and lower part of the vas. If the body of the testis prove to be involved this must be removed also. Radical removal of the seminal tract should be reserved for those cases in which the whole tract is extensively involved, as offering the only hope of relief or as a secondary operation where, in spite of epididymectomy, lesions in the vesicle and prostate become well marked and progressive. Where a renal lesion coexists, this should be dealt with first if practicable. It must be emphasised that in every case there is the possibility of a renal infection being present, and examination of the urine for tubercle bacilli, together with cystoscopy, should form part of the routine examination. Lastly, and most important of all, the general resistance of the patient to the tubercle bacillus must be increased by the methods which have proved efficacious in the treatment of other tuberculous lesions—namely, fresh air, rest, generous fatty diet, and the use of tuberculin.

R. H. O. B. ROBINSON, M.B. Camb., F.R.C.S. Eng.,
Surgeon to Out-patients, St. Thomas's Hospital.

ROYAL MEDICAL BENEVOLENT FUND.—At the last meeting of the Committee 43 cases were considered and £559 voted to 36 applicants. The following are notes on some of the cases relieved.

Daughter, aged 61, of M.R.C.S. who died in 1895. She is now very deaf and has lost the sight of one eye. She looks after an elder sister who is mentally deficient and also takes care of another old lady who pays 10*s.* a week. Income from investments amounts to £34 per annum. The cottage belongs to the two sisters and rates are £2 4*s.* 8*d.* a year. Voted £26.

Widow, aged 37, of L.R.C.P. & S. who died in 1925. Left with six children, 2 to 18 years of age. Since the death of her husband the family have been living on the proceeds of the sale of the practice, which are now exhausted. Applicant borrowed £17. Receives £2 a month from another charity for one child and £5 a quarter from the Freemasons for another. Eldest girl is a typist earning 24*s.* a week. Rent 12*s.* a week. £10 voted and case to be further considered.

Widow, aged 52, of L.R.C.P. & S. who died in 1912. The eldest son, who earns £156 per annum, does not live at home but allows his mother £54 per annum. A daughter, aged 25, is studying for the post office to enable her to secure permanent post. Youngest son, aged 23, earns £78 a year, lives at home, and gives £1 a week towards his keep. Rent £25 per annum. Voted £20 in four instalments, while the daughter is studying.

M.B. Lond., single woman, aged 68, who practised in London and India and then took a home for delicate children which unfortunately failed. Has an adopted child, aged 14, who lives with applicant but attends school. Income from medical work £2 10*s.*, from sale of fruit £3, from paying guests for week-ends £2 10*s.* Allowance from sister of £97. Rent and rates £37. Voted £26 to be paid in quarterly instalments.

M.R.C.S., aged 72, unmarried. Through inability to obtain locums and having exhausted his savings, applied to the Fund for assistance. Receives Epsom College Pension of £30 and old age pension. Voted £30. Total previous relief given £100.

Daughter, aged 54, of L.R.C.P. who died in 1883. She has no income but looks after her mother, aged 87, whose income is derived from the old age pension, the R.M.B. Fund annuity of £30, and from a supplementary grant of 7*s.* 6*d.* a week from our Guild. Voted £18. Has been helped since 1925.

Daughter, aged 61, of L.F.P.S. Glasg. who died in 1897. Only income derived from various charities to the amount of £77 per annum. Fund grant of £18 renewed. This case has been helped since 1914. Total relief £190.

Daughter, aged 68, of F.R.C.S. Eng. who died in 1885. Has been helped by the Fund since 1920, total relief £129. Asks for increased grant until old enough to apply for the old age pension in 1929. Only other income £48 from late father's estate. Voted £30.

Widow, aged 66, of L.R.C.S. who died in 1909. Tries to maintain herself and adopted daughter by taking paying guests. This year only received £126 from this source. Interest on mortgage, rates, and insurance amount to £58. Has been helped by the Fund since 1910, total relief £183. Voted £10.

Subscriptions may be sent to the hon. treasurer, Sir Charters Symonds, at 11, Chandos-street, Cavendish-square, W.1.

Special Articles.

THE CONTENT OF VITAMINS A AND C IN WATERCRESS.

By KATHARINE H. COWARD, D.Sc. Lond.,
AND
P. EGGLETON, M.Sc. Lond.

(From the Department of Physiology and Biochemistry, University College, University of London, and the Pharmacological Laboratories, Pharmaceutical Society of Great Britain.)

THE work here described is partly the result of a suggestion by Dr. H. Scurfield, and partly an extension of an investigation carried out in connexion with the work of Dr. Corry Mann on the feeding of boys of school age (1926). Previous experiments had indicated that watercress (young shoots as eaten in salads) is a rich source of vitamin A. Indeed, it appeared that if allowance were made for about 85 per cent. water in the watercress and about 10 per cent. water in a sample of New Zealand butter with which it was compared, the two materials were equally rich in vitamin A. The experiment which gave this result was carried out in July, 1924, when the metabolic processes of the plant were presumably very vigorous, and it was decided to carry out similar tests at frequent intervals for 12 months, in order to see how far the vitamin A content might vary with the season. For this purpose it was important that the watercress should be obtained from the same source throughout the year, and that it should have had the same treatment in the way of speed of packing, despatch, &c. We were fortunate in securing a suitable supply from the "Sylvasprings" beds at Bere Regis. Baskets were sent direct to the laboratory twice a week, and the three or four days' supply was kept in water in the ordinary daylight of the animal "kitchen." The watercress was the "winter" variety, so-called on account of its hardiness and its ability to thrive in fresh spring water.

The vitamin C content was estimated in September and October of 1925, and the watercress proved to be an exceedingly rich source of this factor also.

Vitamin A in Watercress.

The technique adopted for the test was that in general use in University College, London, at the time.

Rats weighing 45–55 g. were given a basal diet consisting of :—

Caseinogen, "vitamin free"	20 g.	Yeast extract	5 g.
Rice starch	55 g.	Lemon juice	5 g.
Hardened bean seed oil	10 g.	Salt mixture (McCollum's)	5 g.

This was mixed with water to form a stiff paste and given to the rats, fresh each day, *ad lib.* When growth had ceased, the supplement of watercress was given to each rat separately each day. Resumption of normal growth was taken as an index of an adequate supply of vitamin A in the watercress given.

No precaution was taken to give the animals a supply of vitamin D, for it had not been appreciated at that time that vitamin D has growth-promoting as well as antirachitic properties (Steenbock and Nelson, 1923). The animal body can store vitamin D as it can store vitamin A, but if the diet contains neither, growth will cease when the store of either "A" or "D" is exhausted. If only "A" is exhausted, then growth will be resumed when "A" is supplied. If only "D" is exhausted, then growth will only be resumed when "D" is supplied. Most green plant tissue contains very little vitamin D (Boas, 1926, Chick and Roscoe, 1926), hence when animals which have ceased growth on a diet lacking in "A," and probably also in "D," resume growth on being given watercress, it must be assumed that vitamin A was lacking and that the watercress has supplied it, the vitamin D being drawn from the animal's own reserves, or possibly in small amounts from the watercress supplied. While certain of our animals in the long watercress experiment showed normal growth on the doses given, others did not, and in the light of more recent experience we assume that those that did not resume growth had exhausted their reserve of vitamin D, and that their failure to grow was therefore due to a lack of this factor, of which the basal diet supplied little, if any. We did not make calcium estimations of the bones of any of these animals, but we did of others of our stock, and we know from the figures obtained that our animals varied greatly in the calcium content of their bones after six weeks on our basal diet. Hence, presumably, they varied in their original reserves of vitamin D. It was decided therefore to make one further test of watercress on a basal diet containing ample supplies of vitamin D, to see how far the early results had been vitiated by the lack of this precaution, and also to see whether, when the limitation possibly imposed by a shortage of vitamin D was removed, the watercress might not prove to be an even richer source of vitamin A than the early experiments had indicated.

A summary only of the results of the early experiments is given, as it is evident from the later experiment that there was some factor limiting the response to the large doses of watercress then administered.

TABLE I.

—	Date of beginning of test.	Weight of fresh material required for normal growth.
Preliminary test	10/7/24	0·8–1·0 g.
Youngest parts of shoots ..	10/7/24	0·8–1·0 g.
Older green leaves only ..	7/8/24	0·8 g.
Yellowed, but not withered, leaves	7/8/24	0·4–0·8 g.
Stems only	7/8/24	Very poor growth even on 1·6 g.
Shoots— Upper parts	2/10/24	1·0 g.
	11/12/24	More than 0·8 g.
	15/1/25	0·8 g.
	26/3/25	0·4–0·8 g.
	4/5/25	0·4 g.
	4/7/25	0·4 g.

Before discussing the possible significance of the results shown in Table I., the most recent experiment should be described, for in this, by giving the test animals ample supplies of vitamin D in their basal diet, all differences due to variations in reserves of this factor were eliminated, and when they ceased growth it was because their stores of vitamin A were depleted. The technique for this type of experiment differs somewhat from that of the last.

One litter of six rats, weighing 44–49 g., was given a basal diet of :—

Dextrinised rice starch	75 g.	Dried yeast	4 g.
Agar-agar	2 g.	Salt mixture (Steenbock's 40)	4 g.
Caseinogen "vitamin-free"	15 g.		

This was mixed dry, and spread out in thin layers (100 g. over 4 square feet) in zinc trays. These were set under a mercury-vapour lamp at a distance of 2 ft. for half an hour, the lamp running at 2·5 amperes, 130 volts. At half-time the diet was collected and respread in trays to expose a fresh surface. In this way ample supplies of vitamin D were generated in the basal ration (Steenbock and Coward, 1927).

When the rats were steady in weight (the signs of xerophthalmia were very slight) they were given doses of 0, 0·1, 0·2, 0·4, 0·6, 1·0 g. respectively of watercress daily. The smaller doses were single leaflets, the larger were terminal shoots. They were always eaten promptly.

The result of the test is shown in the chart. It is evident that 0·1 g. contains enough vitamin A to promote normal growth when all other necessary factors are present. It should be noted that rat C is a doe and its response is less than that of rat B,

a buck, on a smaller dose, but this is only consistent with the general behaviour of bucks and does of our colony at this point of their growth.

It is evident from Table I. that there is a seasonal variation in the growth-promoting properties of watercress, the most active shoots being formed in the spring and summer months. That light is a potent factor in the formation of vitamin A by living plants has been shown experimentally by

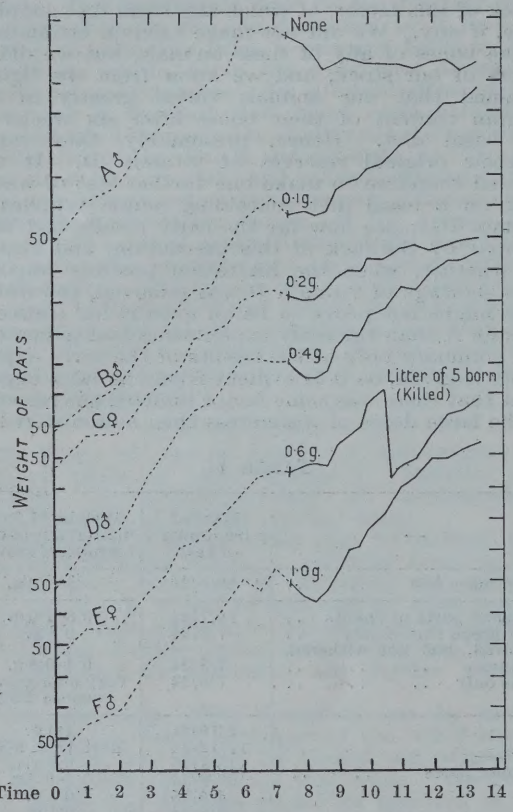

Chart showing weight of six rats over a period of 14 weeks. The weight of each rat at the beginning of the experiment was in the neighbourhood of 50 g. Its subsequent weight at a given period can be estimated from the fact that each division of the vertical ordinate represents 10 g. and each division of the horizontal ordinate represents one week. The dotted line shows their growth before supplements of watercress were given. The rat A served as a control, whilst the others were given small quantities of watercress daily, as indicated. The smallest dose tested (0·1 g.) was sufficient to restore normal growth.

Coward,[1] [2] and that spinach is richer in vitamin D in the summer than in the winter has been shown by Chick and Roscoe. The most recent watercress experiment showed that 0·1 g. of the green leaf contained enough vitamin A to promote normal growth when ample supplies of vitamin D were also given. It would appear, therefore, that in the early experiments which showed a need of 0·4–1·0 g. of watercress, there was probably a shortage of vitamin D; and the fact that less watercress was needed in the summer months than in the winter showed that the shortage was partly, though by no means wholly, removed. It must be concluded that summer watercress, at least, contains some vitamin D, and that it is a most remarkably rich source of vitamin A.

Vitamin C in Watercress.

Little work has been published on the relation of the antiscorbutic value of vegetable tissues with the degree of irradiation of the tissue during growth, but it seems clear that the synthesis of vitamin C can be effected by germinating cereals in darkness, and such synthesis is not demonstrably accelerated by sunlight (Clark, Honeywell and Steenbock, Eggleton and Harris). The watercress used in these tests had grown under favourable conditions of sunlight (August–September), but it does not follow that its antiscorbutic potency was above normal.

Guinea-pigs weighing 200–220 g. were set on the basal diet given below, and given, in addition, measured amounts of watercress shoots fresh daily. Four control animals received no watercress at all.

* Signifies death of animal.

The controls (20–23) displayed symptoms of scurvy after 12–16 days on the basal diet, and survived only another week. At post-mortem all showed definite scorbutic lesions. Of the animals in batch II., No. 24 remained healthy throughout its experimental period, but the others showed, after 3½–5 weeks the slight "hopping" limp typical of mild scurvy in guinea-pigs. The animals in batches III.–VI. were in good health throughout the period of observation. The minimal protective dose of this watercress in the given experimental condition may therefore be taken as 1 g. per day.

Summary.

Watercress is a remarkably rich source of vitamin A, 0·1 g. only of the green leaf being necessary to promote normal growth in a rat which has become steady in weight on a diet lacking this factor only.

It contains also small amounts of vitamin D.

Its growth-promoting properties are even stronger in the spring and summer than in the winter.

It is a very rich source of vitamin C, 1 g. daily being enough to protect guinea-pigs completely for a period of 70 days.

The writers gratefully acknowledge their indebtedness to Mr. W. Bedford, of Bere Regis, for the regular supplies of watercress and to the Medical Research Council who defrayed the cost of almost the whole of this investigation.

SURGICAL TREATMENT OF PULMONARY TUBERCULOSIS.

ABSTRACT OF A LECTURE BY DR. F. HÄBERLIN, DAVOS.

In the course of the recent visit to Swiss sanatoria, arranged by the Council of the Royal Institute of Public Health, a lecture was given in the Rathaus, Davos-Platz, by Dr. Häberlin on the treatment by surgical methods of chronic and intractable cases of tuberculosis of the lung. As in every other branch of surgery, said Dr. Häberlin, the key to success in operations on the lung was a careful selection of cases. There were two main groups which responded favourably to collapse therapy. The first group consisted of those patients who after a more or less prolonged rest-cure lost all toxic symptoms, but in whose lungs there was somewhere a cavity which persistently secreted sputum containing tubercle bacilli. Such patients, if they returned home, would be very liable to start fresh foci of disease, either as the consequence of a hæmorrhage, or as a result of a temporary breaking down of immunity through intercurrent disease, pregnancy, &c. In these cases, which were by far the most favourable, collapse therapy often secured a rapid and lasting result if compression of the cavity could be effected. The second group of patients who were suitable for collapse therapy were those who did not respond favourably to rational conservative measures, whose state of immunity was never balanced, who never lost completely such toxic symptoms as fever, tachycardia, night-sweats, fatigue, and so on, and whose local condition showed no improvement. Many of these patients improved rapidly after the institution of collapse therapy, but it was particularly important in this group to observe the rule of unilaterality of disease. Some authors, especially in Germany, advocated compression in every case of cavernous tuberculosis, but it was quite certain that in a number of cases the cavities disappeared completely after a simple rest-cure, especially those connected with the so-called secondary infiltrations. In all such cases conservative treatment should be tried first, for a patient cured without a pneumothorax was undoubtedly better off than one cured with it.

With regard to the question of the type of collapse therapy indicated—pneumothorax or thoracoplasty—in any given case, Dr. Häberlin said that, provided the pleura were sufficiently free to ensure a good collapse, pneumothorax was indicated: (*a*) in cases of the first group when the cirrhotic retraction of the lung and thoracic wall were not very pronounced and the cavities were of moderate size; (*b*) in cases of the second group of partially exudative character, where there was a definite possibility of reactivation or of fresh infiltration on the healthy side (in such cases it was always possible to interrupt a pneumothorax treatment, whereas a rib-resection was irreversible); pneumothorax was also indicated (*c*) where compression was urgent (e.g., rapid increase in the size of cavities, hæmorrhage, &c.), but where there was uncertainty as to the inactivity of the other side; and (*d*) in those patients whose general condition was not good enough to stand the shock of a big operation. Thoracoplasty, on the other hand, was indicated: (*a*) with pronounced cirrhotic retraction of lung and thoracic wall; (*b*) if the cavities were large; (*c*) where pneumothorax was impossible on account of adhesions. The results of pneumothorax treatment varied within wide limits according to different authorities, from 21 per cent. of cures in Heiligenschwendi to 40 per cent. claimed by Dr. Staub, or 73 per cent. if only the period 1918–23 were considered. These discrepancies were explained by the different character of cases submitted to the operation, by the duration of observation before, and of sanatorium treatment after it, and by the measure of painstaking follow-up work of tuberculosis dispensaries. If these results were compared with the fate of patients who had been considered suitable for collapse therapy, but who had either refused the treatment or had been unable to obtain it owing to pleural adhesions, it would be found that 80 to 90 per cent. of the patients were already dead, and the few who were still in good health usually owed it to the fact that they had continued to work and to live in Davos. The risks of thoracoplasty were, of course, much greater, Sauerbruch estimating the actual operation mortality as 13 per cent. This high rate showed that they still operated too often on patients who were not fit for operation, but it was also true that even in apparently hopeless cases the operation sometimes saved lives that would otherwise be lost. Thus a surgeon who did not think primarily about his statistics would probably continue to operate on such risky cases, knowing that the operation offered a last, though small, chance of recovery.

In conclusion Dr. Häberlin referred briefly to the exairesis of the phrenic nerve, either as a prelude or an alternative to pneumothorax or thoracoplasty, and showed a large number of X ray plates to illustrate his points.

PARIS.

Substitutes for Insulin.

ALTHOUGH the action of insulin given by injection is definitely established, the many attempts to administer it in other ways have had no conclusive results, and in France the tendency is to keep Banting's admirable remedy for three classes of case: (1) diabetes with serious developments; (2) diabetes accompanied by tuberculosis; and (3) cases in which a preparatory course of treatment is required. There is some hesitation before prescribing daily doses in uncomplicated cases, and it is considered preferable to do no more than limit the diet. This being so, there is an obvious opening for drugs which, although less efficacious, can be taken by the mouth, and experiments have been made with the two German preparations, synthalin and glucoferment. There is no doubt that these two drugs will lower the blood-sugar, but they cannot be compared to synthalin in efficacy, and cannot replace it in serious cases. The objection to synthalin is that it produces digestive disturbances; glucoferment is better tolerated. The two preparations are chiefly useful when the aim is merely to increase the amount of food taken. Although their action is not wholly satisfactory, it is beyond dispute that in the absence of insulin their discovery would have been thought a great step forward, and they do lend hope that some day it may be possible to find an oral remedy for diabetic glycosuria.

Treatment of Broncho-pneumonia in Childhood.

No longer do we accept the simple view that sera are purely curative and vaccines purely preventive in their action. Thus vaccines have been shown to have definite therapeutic value in the broncho-pneumonia of infants, though serum is used in conjunction with them because by themselves they act but slowly. Opinions expressed at the recent congress on pædiatrics at Geneva were clearly in favour of the simultaneous use of antistreptococcal serum and vaccine in this form of pneumonia. Although, however, the figures of the last two years show improved results in treatment, it is far too soon to boast about them. The success of these bacteriological agents does not justify us in dispensing with the classical means of combating pneumonia, whose value time has proved, and at present the new methods must be regarded as no more than supplementary.

Dried Milk Fever.

It has sometimes been noticed that babies brought up on dried milk develop bouts of high fever, with no other evidence of disease; this fever abates as soon as dried milk is no longer given. Rare though it is, this condition is sufficiently troublesome to deserve notice. Its origin does not seem to be an infection,

and the best explanation seems to be that of Dr. Lust, who puts it down to the toxic action, on the heat-regulating centres of specially sensitive children, of a preparation containing salts in high concentration.

Insulin in Obliterative Arteritis.

Before having recourse to surgery, an attempt should be made to treat arteritis obliterans by medical means. Radiotherapy and diathermy may be used, but sometimes insulin is equally successful in cases of intermittent claudication and even angina pectoris. I have had one case in which a patient on this treatment was able to walk better after a few days, his range of movement increasing from several yards to several hundred yards within two or three weeks. He put on weight, his general condition improved, and his pain disappeared. It must be noted that in the reported cases no objective sign of vascular degeneration had been detected, and it is clear that treatment has to be continued for a very long time. Subcutaneous injections of 10 units of insulin can be given once a day for one or two months, and if the results are encouraging the dose can then be reduced.

Acute Rheumatism.

The acute articular rheumatism of childhood should not be regarded as an acute affection with relapses, but rather as a prolonged disease with exacerbations. Rheumatism is above all a carditis, and should be looked on as one of the chronic diseases of which syphilis is the type. This idea, developed in France by Bezançon and Matthieu Pierre-Weil, furnishes a rule which can be closely applied in treatment. The object is, in the first attack of rheumatism, to sterilise the body, and this is done by giving very large doses of salicylate of soda over several months. The drug is administered in rheumatism with the same object as arsenic, mercury, or bismuth are administered in syphilis. By combining it with equal parts of bicarbonate of soda much larger doses can be given than were formerly usual, and in certain cases a dose of 12·0 g. can be prescribed.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Retrospect of the Tropical Medicine Congress.

THE success of the Seventh Congress of the Far Eastern Tropical Association, held in Calcutta from Dec. 5th–24th, exceeded all our expectations. It has been the largest and the most interesting Congress held under the auspices of the Association; some 900 members attended, and a large proportion took part in the discussions. An attractive episode was the luncheon given by the Rotary Club of Calcutta, at which Colonel J. D. Graham, Public Health Commissioner with the Government of India, outlined the activities of the League of Nations in preventing the spread of epidemic diseases along the highways of traffic and commerce throughout the world. Delegates on their way to and from the scientific discussions were reminded of the historical background to modern hygiene by the progress of the sacred bull throughout the teeming thoroughfares of the city. The spacious grounds and buildings of the Medical College afforded ample space for the Sections which overflowed from the adjacent Tropical School of Medicine.

The Scientific Sections.

The Section of Medicine opened with a remarkable paper by Lieut.-Colonel F. A. F. Barnardo, I.M.S., Principal of the College, on multiple and secondary infections in tropical diseases. By recognising and treating the secondary factor in the course of enteric fever the author claims to have removed most of the terrors of a disease which is a constant menace to Europeans in the tropics. Dr. Wu Lien Teh's paper on pneumonic plague was equally enlightening, and there was general agreement on the best lines for investigation to take in bubonic and pneumonic plague epidemics. A joint discussion between the Association and the League of Nations Plague Subcommittee gave promise of material advance in preventive methods. The Malaria Section met over four days. Malaria control was introduced by Sir Malcolm Watson, and Lieut.-Colonel S. P. James, I.M.S., recounted the fascinating experiments being made in England on the treatment of induced malaria. Discussion showed opinion to be converging towards a definite pronouncement as to the most advantageous combination of antilarval measures with drug administration. The Cholera Section discussed the administration of bilivaccine, and considered the epidemiology of the disease from many aspects. In the Deficiency Diseases Section Lieut.-Colonel R. McCarrison's persuasive introduction failed to reconcile the two schools of thought on the ætiology of beri-beri and epidemic dropsy. Dr. F. d'Herelle read a series of papers on bacteriophagy in relation to cholera and dysentery, and should his discoveries be corroborated, a new aspect of immunity must be reckoned with. Discussion in the Leprosy Section revealed the notable advances made in the treatment of this disease, and the fact that cure is not only possible but probable in all the more favourable cases.

The New Outlook.

There is no question that the Congress visitors must have gained a profound impression of the wealth of clinical material in India, especially in Bengal, and it is to be hoped that the discussions may be the starting-point of a new era in research and of an organised and systematic record of clinical observations of cases. Add to these a scientific critical assessment of the value of such observations, hitherto so noticeable by its absence among the indigenous medical profession, and we should be on the eve of a great advance in the pathology and epidemiology of the more common diseases of India. Official delegates will have seen reason to press their Governments, central or provincial, for a definite declaration of policy on the two chief needs of the time: (1) A health policy for India associated with the formation of a Ministry of Health; (2) A definition of the standard of medical education to be reached at medical schools and colleges which will enable their graduates to carry out this policy. If the difficulty in issuing such a declaration of policy is purely financial, it is to be hoped that the Government of India will not hesitate to invoke the aid of the Rockefeller Foundation, even if that would involve some loss of control of the actual measures to be adopted. The need is urgent. Preventive medicine is still unorganised in India, medical education is decades behind medical science, and it may be necessary for the League of Nations to reinforce the representations which have been made by every department of preventive medicine and every research worker in India.

The Burden of Malaria.

The prevalence of malaria after the monsoon throughout the whole of India has again drawn attention to the extreme seriousness of this disease not only in terms of mortality, but also as a factor of inefficiency. In Calcutta itself the mortality has risen from 1·4 per mille in 1924 to 1·6 per mille in 1926. Many educational centres show an average absenteeism from college or school of seven days per student per annum from malaria alone. This is serious enough from the educational standpoint, but leaves untouched the industrial aspect. The possibility of obtaining a body of healthy malaria-free labour in the country is at present very remote. No disease in the tropics repays scientific investigation more than does malaria, if a concentrated survey be first undertaken on rational principles. The earlier favourable reports regarding the use of plasmochin as an antimalarial remedy do not appear to have been thoroughly substantiated, except in the case of subtertian fever. Its advantages over the clumsy quinine salts are

many and obvious, but difficulties arising from its toxicity have not been eliminated. Until a less toxic preparation has been devised it can hardly become a popular remedy capable of being distributed to infected populations at large.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Painless Treatment of Leprosy.

FOR some time experiments have been carried on at the National Leprosarium at Carville, Louisiana, with the object of finding a painless and efficient method of administering chaulmoogra oil. Among the oil-soluble analgesics benzocaine has been found the most satisfactory, and after animal and human experimentation the following formula was adopted for routine treatment of several cases.

Chaulmoogra oil	90
Olive oil	10
Benzocaine	3

The preparation is described as follows:—

"Three grams of benzocaine are added to 10 c.cm. of olive oil and mixed with a stirring rod; this is then added to 90 c.cm. of chaulmoogra oil previously warmed on water bath to 70° C.; the oil mass is then agitated in a flask until all remaining crystals of benzocaine are dissolved. The mixture is filtered through filter paper and then heated on water bath at 100° C. for one hour."

As a routine dosage 5 c.cm. of this mixture is given in the deltoid region, alternating semi-weekly with 8 c.cm. in the buttocks, the oil being injected at body temperature. Preliminary case reports with illustrations have appeared in the weekly reports issued by the U.S. Public Health Service. Dr. Johansen is now investigating whether the addition of benzocaine may make it feasible to administer chaulmoogra oil by the mouth.

Christmas under Prohibition.

It is yet too soon to say how great will be the mortality from "wet" celebrations of Christmas and the New Year, but it is safe to forecast that many will die from poisoning. The extra demand at this season cannot possibly be met from the stores of smuggled liquor. Immature "moonshine" will be mixed with denatured alcohol and sold no doubt as "Pure Scotch." Alcohol denatured by the Government is now said to contain formaldehyde, 1 per cent.; pyridine, 1 per cent.; diethylphthalate, 1 per cent.; wood alcohol, 0·5 per cent., and bichloride, 0·1 per cent. Commercial chemists who test liquor to determine its safety for drinking purposes violate the law in so doing, and are to be prosecuted, according to instructions issued by the Commissioner, in Washington.

Artificial Respiration in Infantile Paralysis.

In cases of poliomyelitis, wherein the respiratory centre becomes affected, artificial respiration has often been resorted to in a desire to prolong life. I have not heard of any case in which life has been saved by this procedure, but there is reported from Oconto, Nebraska, the case of a 16-year-old girl who has been kept alive for 34 days by this method. It is said that some hope of her ultimate recovery is entertained.

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Work of the Irish Medical Committee.

AT a recent meeting of the Irish Medical Committee held in Dublin it was resolved that the Minister for Local Government and Public Health be requested to receive a deputation in connexion with (1) the inadequate salaries of poor-law medical officers in co. Mayo, co. Longford, and elsewhere; (2) the appointment of locum tenents nominated by doctors going on leave; (3) promotion under the Local Authorities (Officers and Employees) Act, 1926; (4) remuneration for registrars of births, deaths, and marriages; (5) fees for committal of dangerous lunatics; and (6) arrangements for the treatment of private patients in district and county hospitals. It was also decided that representations should be made to the Appointments Commissioners as follows: (1) that a recurring fee of £1 for medical candidates appearing before different Selection Boards is excessive; (2) that candidates with no prospect of being appointed should not be put to the expense of appearing before the Selection Boards unless on the expressed desire of the candidates; (3) that the physical examination appears unnecessarily severe, and that it should have a direct relation to the physical requirements necessary for the efficient medical discharge of the duties of the office to be filled; (4) that, if required, medical members of Selection Boards should receive reasonable remuneration. Amongst other business discussed was the question of pensions and fixity of tenure for medical officers in the Free State Army, and it was agreed that such medical officers should be engaged on a permanent and pensionable basis.

Medical Certificates and the School Attendance Act.

A good deal of trouble is being caused to medical practitioners in the Irish Free State, especially to those engaged in the poor-law service, by the working of the School Attendance Act. The Act provides that the production of a medical certificate of illness of the child should be a good defence in cases where the parents are prosecuted for non-attendance of a child at school. It makes no provision, however, for such certificates to be given or to be paid for, leaving the onus on the parents. In most cases the parent is unable to pay a fee for a medical certificate, and in many cases there is no medical man in attendance. Poor-law medical officers who were at first inclined to give certificates gratuitiously, as a matter of charity, have found that this kindness has increased their work unexpectedly. They are now sent for to visit children suffering from trivial illnesses in the hope that, in the event of questions being asked as to the child's absence from school, a certificate may be obtainable. The position is unsatisfactory, and the Irish Medical Committee has decided to recommend medical men to refuse to grant any certificates in school attendance cases.

Annual Dinner of the 83rd (Dublin) Hospital.

The annual dinner of the members of the Dublin unit of the 83rd (Dublin) Hospital, who served when the hospital was at Boulogne in 1917–18, was held last Saturday at the Royal College of Surgeons, Dublin. Colonel Sir William Taylor, who organised the unit, was in the chair, and 15 other members were present.

MEDICINE AND THE LAW.

Criminal Neglect of Health.

THERE have been several recent reminders of the penal consequences of omitting to obtain adequate medical aid for those who require it. A coroner, investigating a death due to cancer, found that treatment had been given by an untrained woman described as a herbalist. He pointed out that, if the patient's disease had not already been far advanced before such treatment began, the herbalist might well have found herself in the dock on a charge of manslaughter. A month ago at the Central Criminal Court a charwoman, aged 60, was charged on indictment and on a coroner's inquisition with the manslaughter of her daughter. Ten months earlier the daughter had disappeared; it was afterwards found that for the whole period she had been living in her mother's room in Walworth in a state of hideous neglect and

indescribable filth. The mother never informed anyone of her daughter's ill-health and never called in a doctor. The medical evidence proved death was due to blood poisoning consequent upon an ulcer of the hip-joint and general neglect, and that medical attendance would have saved the daughter's life. There was some doubt of the prisoner's sanity, but she was found fit to plead and take her trial. She was found guilty and sentenced to ten years penal servitude.

The same problem of legal insistence upon recourse to medical aid has arisen in cases which fall far short of manslaughter. Parents fail sometimes to realise the duty placed upon them by Section 12 of the Children Act. They may be genuinely affectionate and kind towards their children; they may be far from committing any act of deliberate cruelty such as that section punishes; but they are unaware that the section also makes it a misdemeanour to neglect a child "in a manner likely to cause unnecessary suffering or injury to health," and that these words have been held to cover a parent's refusal to allow an operation upon his child for the removal of adenoids or enlarged tonsils. A prosecution of this nature was brought last month against a Cumberland farmer and his wife. The medical authorities of the county had for four years been trying to have the operation performed, but the parents (though in other respects exemplary) invariably refused permission. The magistrates adjourned the case for a month in order that the operation might be carried out, the prosecution intimating that, if the operation took place, the summons would be withdrawn. Though the requirement of the law may take some people by surprise, there is no doubt whatever of the legal position. One of Mr. Justice Darling's last decisions in the Divisional Court made it perfectly clear that, if the justices are satisfied upon the medical evidence that failure to allow an operation would cause unnecessary suffering, the parents will be held responsible under the criminal law.

Public Conveniences at Railway Stations.

It has recently been stated that sanitary conveniences are no longer being provided at the stations of the underground railways in London. It seems to be the fact that, in rebuilding the St. James's Park and Piccadilly Circus stations (where the local authority has already provided sanitary accommodation in the street outside), the railway company concerned has made no such provision. Some may wonder whether London is already sufficiently equipped in this respect or whether it is not a mistake to miss any chance of maintaining and supplementing the existing facilities when the population (of both sexes) which daily frequents London seems to be constantly increasing. The old-fashioned urinal, too conspicuous perhaps for modern tastes, has largely disappeared from the surface of our streets. The needs of street traffic, as well as æsthetic considerations, have driven it underground where modern engineering manages to make a greater area available for greater requirements. But public conveniences cannot be made invisible without creating a situation of hardship, especially for strangers who visit the metropolis.

The Public Health Act of 1907 empowered local authorities (in districts where the Act was in force) to require urinals to be attached to all public-houses, refreshment rooms, and places of public entertainment. The statutory requirement for railways was less direct. The Railway and Canal Traffic Act of 1854 requires railway companies to afford reasonable facilities for receiving, forwarding, and delivering traffic, and in this context "traffic" is defined as including passengers. Naturally the scope of what is reasonable was much debated in the courts. In 1894, for example, Mathew J. declared a cloak-room to be the most reasonable of facilities at a railway station, and on the same occasion Collins J. (afterwards Master of the Rolls) spoke significantly of the "rising standard of convenience to which railway companies are obliged to conform." In the following year the West Ham Corporation, in an action against the Great Eastern Railway, elicited the decision that the omission to supply free water-closets for passengers' use was not a denial of reasonable facilities; this decision, however, was not unanimous, for Sir Frederick Peel (one of the Railway and Canal Commissioners) took the view that railways should be compelled to give such accommodation without payment. The underground railways in London are, of course, in a special position. Their space below ground is not unlimited; it may even be below sewer level; and their journeys are short. Nevertheless there seems no reason why the ever-increasing crowds of passengers should be denied facilities at any single station or be left in doubt as to which station contains what they require. The big London shops and stores long ago realised that the provision of lavatory accommodation was an attraction to customers if not indeed a positive duty. If the railways—whatever their freedom from statutory obligation—should take the same view, the public will undoubtedly be grateful.

Public Health Services.

DISSATISFACTION AT DUNDEE WITH PANEL PRACTICE.

WE learn from the report of the Dundee Panel Committee for 1927, which reached us just as the year turned, that the past year has been characterised by a feeling of dissatisfaction and insecurity among panel practitioners in the third largest Scottish burgh. This is at first sight surprising in view of the fact that the National Health Insurance scheme has become elsewhere such an integral part of our everyday life as to lead to tacit acceptance of its benefits. We need do no more than recall a remark made by the Royal Commission in 1926 ("We are satisfied that the scheme of national health insurance has fully justified itself and has on the whole been successful in operation") and the more recent statement of the Chief Medical Officer to the Ministry of Health that through this scheme "the four means of preventive medicine—compensation, early restoration, rejection of morbid sequelæ, and positive hygiene teaching—are being applied in one form or another to seven million patients every year." It is therefore a matter for earnest inquiry what has created the adverse feeling among the medical men and women who serve the large industrial population of Dundee. The feeling, it is stated, is due to a variety of causes, but it does not appear from the report that Dundee practitioners take objection to the terms of their service or to their contract with the insurance committee. The feeling seems to be due rather to the administration of the Act and of the Regulations framed under it. The most pressing cause of dissatisfaction is "the apparent inadequate remuneration received by the doctors." The remuneration this year, the report states, "promises to work out about 8*s.* 1½*d.* per head, which shows a still more marked reduction from the agreed average of 9*s.* of which the only explanation offered is the alleged inflation." Now, whatever may be urged against the method of remuneration under the Acts, the method itself is clear and above board. Panel practitioners themselves are directly represented on the central distribution committee, which settles the quota for each year and distributes the available money (dependent upon the number of insured persons paying contributions) among those who treat insured persons resident in their area. The number of credits given to each practitioner does not, of course, necessarily represent a corresponding number of insured persons, for the number is a mean, as it is impossible for any practitioner to say how many persons are on his list at a particular time. The insurance committee's register is dependent upon notifications from approved societies of the names of new members, these being in turn dependent upon the reports of agents. Error

made at the outset cannot be corrected until the surrender of contribution cards at the end of the period, when the processes of inflation and deflation, which are constantly going on, are balanced one against the other. It is unfortunate that the process of elimination does not take place at the same rate as the process of aggregation, for then the payment to a practitioner would be an exact multiple of the capitation fee by the number of insured persons on his list, but it is difficult to see how Dundee practitioners have arrived at the conclusion that they are receiving 8*s.* 1½*d.* instead of 9*s.* per head, seeing that the final settlement for the year cannot be made until the final credits are known. Inflation is unavoidable. It may be kept down to reasonable limits by clearance schemes, but no method has been devised to abolish the difficulties of registration which are due in large measure to ignorance and fecklessness on the part of the insured population which has not learned to play its part in the scheme. Many insured persons lose their medical cards or refuse to surrender them when asked for. But the central pool is nevertheless duly credited with the fees and the whole of this pool is duly distributed among insurance practitioners.

Other causes of dissatisfaction are said to be the spread of erroneous information by agents of the societies, but this, however annoying, can hardly affect the practitioner's actions which are governed by the regulations and by his own sense of duty. Some concern at the increase in sickness benefit is inevitable, for it is so enormous as to imperil the proper administration of the scheme. It will, we fear, be found on investigation that there is a genuine increase in the amount of disabling sickness and that this explains in part the unparalleled demands upon medical service. But it should not be forgotten that insured persons are learning to attend in the earlier stages of illness and that more work of a preventive nature is being done. After these factors have been taken into account there may (or may not) be a margin of careless certification due to the coercion of practitioners by insured persons who desire to get some cash return for their contributions. The recent limitation on the right of insured persons to transfer at any time is a welcome addition to the practitioner's armoury against this kind of attack.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED DEC. 31ST, 1927.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 247 (last week 255); scarlet fever, 1595; diphtheria, 1153; enteric fever, 29; pneumonia, 1802; puerperal fever, 34; puerperal pyrexia, 89; cerebro-spinal fever, 3; acute poliomyelitis, 8; acute polioencephalitis, 1; encephalitis lethargica, 37; dysentery, 11; ophthalmia neonatorum, 61. There was no case of cholera, plague, or typhus fever notified during the week.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 60 (14) from measles, 6 (0) from scarlet fever, 32 (10) from whooping-cough, 53 (13) from diphtheria, 59 (19) from diarrhœa and enteritis under two years, and 128 (24) from influenza. The figures in parentheses are those for London itself. If the return were complete it would imply an agreeable drop in the mortality from measles, but the figures are admittedly affected by delayed registration owing to the holidays. Of the 46 fatal cases outside London 9 were reported from Bristol, 11 from Manchester, 2 from Salford, 1 from Warrington, and 3 from St. Helens; while the figures from Glasgow and Dublin for the same week were 45 and 13 respectively. The deaths from enteric fever outside London occurred in Preston and Darlington, one each. The number of stillbirths registered during the week was 283 in the great towns, including 49 in London.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdr. W. J. Colborne to *Impregnable*.
Surg. Lt. C. T. Hyatt to *Vivid*.
Surg. Comdr. L. F. Cope is placed on the retd. list with the rank of Surg. Capt.

ROYAL NAVAL VOLUNTEER RESERVE.

Surg. Comdr. R. Wilbond is placed on the retd. list and to be Surg. Capt. (retd.).
Surg. Lt. R. Hall to be Surg. Lt.-Comdr.
Proby. Surg. Lt. R. L. Stubbs to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS.

The undermentioned are apptd. Cols. Comdt.: Maj.-Gen. Sir M. P. C. Holt, late R.A.M.C., vice Maj.-Gen. Sir W. G. Macpherson.
Maj.-Gen. Sir S. G. Guise-Moores, retd. pay, late R.A.M.C., vice Lt.-Gen. Sir A. T. Sloggett.
Lt.-Col. A. C. Adderley, half pay list, late R.A.M.C., retires on retd. pay on account of ill-health.
Maj. H. H. A. Emerson to be Bt. Lt.-Col.
Maj. B. H. H. Neven-Spence retires on retd. pay.
Lt. (on Prob.) T. F. M. Woods from the secd. list, is restd. to the estabt.
Temp. Lt. S. M. Burrows to be Lt. (on prob.).

ARMY RESERVE OF OFFICERS.

Lt.-Col. H. B. G. Walton having attained the age limit of liability to recall, ceases to belong to the Res. of Off.
Lt.-Col. R. G. H. Tate ceases to belong to the Res. of Off., on account of ill-health.

INDIAN MEDICAL SERVICE.

The undermentioned officers retire: Col. G. Browse and Lt.-Col. W. W. Jeudwine.

COLONIAL MEDICAL SERVICES.

Dr. W. E. Burton, District Medical Officer, St. Kitts, to be Principal Medical Officer, British Honduras; Dr. C. T. MacCarthy, late Government Medical Officer, British Guiana, to be Medical Officer, Federated Malay States; Dr. D. Duff, Senior Medical Officer, to be an Assistant Director of the Medical Service, Gold Coast; Dr. S. L. Brohier, Medical Officer, to be a Senior Medical Officer, Gold Coast; Dr. K. K. Grieve, Medical Officer, to be a Senior Medical Officer, Nigeria; Dr. W. E. Glover, Medical Officer, to be a Senior Medical Officer, Nigeria; Dr. R. B. Hawes, Medical Officer, Straits Settlements, to be Professor of Medicine in the College of Medicine, Singapore; and Dr. V. L. Ferguson, Resident Surgeon, Colonial Hospital, Grenada, to be Chief Medical Officer, St. Lucia. Mr. J. P. M. Donelly, Mr. W. S. Thomas, and Mr. A. Reid to be Medical Officers, West African Medical Staff; Mr. A. V. G. Price to be District Medical Officer, British Solomon Islands Protectorate; Mr. E. C. Morris and Mr. W. E. Holmes to be Medical Officers, Federated Malay States; Miss V. E. K. Stuart to be Lady Medical Officer, Federated Malay States; and Lt. E. L. Robert to be Medical Officer, Straits Settlements.

DEATHS IN THE SERVICES.

Lt.-Col. Francis Edward Swinton, C.I.E., late I.M.S., whose death at the age of 60 is reported from Bombay, was the eldest surviving son of the late Robert Blair Swinton, of the Madras Civil Service. He received his medical education at St. Bartholomew's Hospital, and after qualifying with the conjoint diploma entered the Indian Medical Service and was for some years medical officer of the 28th Bombay Pioneers. Later he acted as personal assistant to the principal medical officer of the Bombay Command, and was medical storekeeper for the Government of Bombay. Subsequently he became Deputy Director-General of the Indian Medical Service, and afterwards medical storekeeper to the Government of Madras. He received the C.I.E. in 1919 and retired in 1922.

Major-General Sir James Maher, late R.A.M.C., who died on Jan. 7th, aged 69, was the youngest son of Mr. John Edward Maher, of Liskelly, Galway. Educated at Monaghan and Dublin, he qualified as L.R.C.P. & S. Edin. in 1883, and joined the Army Medical Service in 1885, when he served in the Sudan operations. Later he took part in the Ashanti campaign of 1895–96. In the late war he was successively Deputy Director of Medical Services, Lines of Communication, Mediterranean Expeditionary Force; Director of Medical Services, Egypt; and Deputy Director of Medical Services, Irish Command. He received the C.B. in 1916 and the K.C.M.G. in 1918, in which year he was promoted major-general. Sir James Maher married, in 1902, Gertrude, daughter of Mr. J. F. Browne, of the Bengal Civil Service.

"Audi alteram partem."

GASTRO-DUODENAL ULCERATION.

To the Editor of THE LANCET.

SIR,—Prof. MacLean and his collaborators have performed a useful service by publishing a series of cases of gastric and duodenal ulcer, with radiograms before and after treatment, in which healing has been brought about by medical means. They thereby confirm the published and unpublished results of many physicians in this and other countries. The value of their conclusions would, however, have been greatly enhanced if they had not been partly based upon assumptions which seem to me unwarrantable in the present state of our knowledge.

The first assumption is embodied in the use of the word "cure"—always an unwise word for the physician to employ excepting in specific diseases for which we possess a specific remedy. Medical treatment can undoubtedly expedite the healing of an active ulcer and in a high proportion of well-selected cases this healing may be long enduring or permanent, but in my experience it is not justifiable to speak of a group of cases of gastric ulcer as "cured," and of their recurrences as "extremely rare" when they have only been watched for periods of a year or less. Most of the cases reported in Prof. MacLean's paper began their treatment less than a year ago. If he will report again on the same and additional cases in five and ten years' time, the efficacy of his treatment and after-treatment will have stood a better test and he will then be better able to assess factors favourable or adverse to the permanent healing of ulcers.

A second assumption is that the effects of the treatment are to be attributed to the alkalis as employed. From the text one would gather that the quick disappearance of symptoms and the later disappearance of radiological evidences of ulceration were to be attributed to this particular method. As a matter of fact, the majority of ulcer patients lose their symptoms within 48 hours of going to bed on a soft diet with properly spaced feeds, and ulcers can also be shown (radiographically) to heal in a few weeks on a variety of treatments in which the intensive employment of alkalis does not necessarily play a part.

A third assumption is that the control of acidity can "easily" be achieved by this or any other method. Unless it can be shown with the aid of the continuous test-meal that this has been accomplished in a number of cases with varying degrees of gastric acidity, this statement must be accepted with reserve. Prof. MacLean speaks of alkalosis as a bogy. It may be rare nowadays, but those who have followed the literature and have themselves seen patients both slightly and seriously ill from alkalosis in the early days of intensive alkaline therapy will not be prepared to agree with him in this. Furthermore, there are other contra-indications to intensive alkaline treatment besides renal disease and chief among these is pyloric stenosis, some cases of which he seems to suggest may be suitable for treatment by this method. Finally, it is difficult not to read into the paper as a whole an undercurrent of assumption that the method has a claim to originality. In this regard it is a pity that it includes no proper reference to the writings of Sippy or Hurst.

I do not advance these criticisms from any sense of opposition to medical treatment, of which (with judicious selection of cases) I am a staunch advocate, but because I believe it is of the greatest importance in matters of this kind to base our contentions on sound and well-weighed evidence. We are looking to the units, with all their facilities for research and follow-up inquiries, whenever possible to supply us with such evidence.—I am, Sir, yours faithfully,

Wimpole-street, W., Jan. 7th, 1928. J. A. RYLE.

To the Editor of THE LANCET.

SIR,—We have for so long practised and taught the important principles embodied in the paper by Prof. MacLean and his co-workers in your issue of Jan. 7th, that we hasten to express our appreciation of this additional confirmation of the value of the treatment of gastric and duodenal ulcer which we owe to the genius of the late Bertram Sippy. The use of alkalis in gastric disease dates back at least to the sixteenth century, the principle of small frequent feeds had been employed with uncertain success for fully 50 years, it was the application of the two principles with rigour and logic that enabled Sippy to evolve the treatment which has yielded the gratifying results experienced by so many observers in all countries during the last decade.

The evidence that peptic ulcer, even when deeply penetrating the tissues in the region of the lesser curvature of the stomach, will heal when so treated has become abundant since radiography has been employed in following up the cases. In conjunction with Dr. F. G. Nicholas, one of us published a communication in the *British Medical Journal* last June giving the results in a series of such cases studied with the aid of X rays at the Middlesex Hospital and including a survey of existing literature on the subject. The papers by Einhorn and Crohn, and by F. W. White in recent numbers of the *American Journal of Medical Sciences*, and by Moutier and Porcher in the *Presse Médicale* of Sept. 7th, may be taken in conjunction with Prof. MacLean's article as supplying still later refutation of the astonishing doctrine, upheld by certain surgeons, that gastric ulcers can never be made to heal.

We feel, however, that there are two very important points to which Prof. MacLean and his co-workers give insufficient attention in their article; the first is, that foci of infection, particularly in the mouth, must be eradicated. It is widely accepted that such foci are the commonest causes of ulceration by producing bacterial emboli, and unless they are removed there must always be grave risk of recurrences. The second point is the importance of diet. The administration of small, easily digestible feeds of high caloric value, at short intervals, not only diminishes both peristalsis and the excitation of secretion, but repeatedly provides the stomach with neutral material, whose buffers tend to lower acidity to an extent almost as great as that produced by the alkalis. We are in agreement with many British and foreign observers, of whom Alvarez may be quoted as a prominent exponent, in finding that if a convalescent patient is trained to take a little milk or to nibble a dry biscuit between his small meals he will remain as free of symptoms as if treated with alkali on a less careful diet. Moreover, if the patient comes from a class where it is impossible to expect him to continue treatment in a thorough manner for a long period, it is easier to persuade him to take dietetic precautions than to submit to the use of medicines for more than six months.

Embodying as it does nothing more than the main principles of the Sippy treatment, the paper of Prof. MacLean and co-workers is one with which practically all physicians experienced in the modern treatment of gastric ulcer will agree. It is perhaps to be regretted that a paper has come from a medical unit without reference to the extensive current literature on this subject, and we feel, in addition, that longer experience with the modern method will lead Prof. MacLean and his co-workers to be more judicious in their use of the word "cure" unless they pay increased attention to the factors of sepsis and diet to which we have referred above.

We are, Sir, yours faithfully, T. IZOD BENNETT
ALAN MONCRIEFF

London, W., Jan. 9th, 1928.

DEATH REGISTRATION AND THE FATALITY-RATES OF SMALL-POX.

To the Editor of THE LANCET.

SIR,—It is an almost universal medical belief (and I share this belief) that the fatality-rate among persons attacked by small-pox is much greater, age for age, among the unvaccinated than among the vaccinated. An apparent contradiction is furnished in the small-pox statistics [1] of England and Wales for the four years 1923–26. The following table furnishes the numbers of cases of "small-pox" in vaccinated and unvaccinated persons over 15 years of age, together with the numbers of deaths and the fatality-rates per cent. for each of these years and for the whole period. The comparison is confined to age 15 and over for the simple reason that practically all the cases under 15 are among the unvaccinated.

	VACCINATED.			UNVACCINATED.		
Year.	Cases over 15 years.	Deaths.	Case-mortality per cent.	Cases over 15 years.	Deaths.	Case-mortality per cent.
1923	369	2	0·5	734	2	0·3
1924	635	2	0·3	1241	—	—
1925	933	3	0·3	1824	—	—
1926	2073	6	0·3	*3116	2	0·06
Totals	4010	13	0·3	6915	4	0·06

* Including 94 cases "doubtful" as to vaccination state.

The figures are, of course, too small to carry any great weight, but it will be observed that in each year the fatality-rate was greater among the vaccinated than among the unvaccinated. In a total for these four years of 11,019 cases, 4010 occurred among the vaccinated with 13 deaths (a fatality-rate of 0·3 per cent.) and 6915 occurred among the unvaccinated with four deaths (a fatality-rate of 0·06 per cent.) That is to say, the fatality-rate among vaccinated cases was just five times as great as among unvaccinated cases. It would be interesting to read possible explanations of this statistical anomaly which your readers may have to offer. Clearly some explanation is required, in justice to vaccination, and if, as I believe, the anomaly is due to faulty registration, the figures seem to me to call urgently for :—

1. A special inquiry into the *true* cause of death of all fatal cases of "mild small-pox" in this country.

2. Revision of the rules of death registration under which a death certified by the doctor in attendance as due to chronic nephritis, cerebral hæmorrhage, or other disease or condition unconnected with small-pox is registered and entered in the vital statistics as a death from small-pox.

I am, Sir, yours faithfully,

R. P. GARROW,
Medical Officer of Health and School Medical Officer,
Jan. 4th, 1928. Chesterfield.

AURAL SYSTEMIC INFECTION.

To the Editor of THE LANCET.

SIR,—In your issue of Dec. 31st, 1927 (p. 1390) Mr. R. D. Owen describes a case of "aural systemic infection" and attributes the nephritis, arthritis, bronchitis, and empyema to the mastoiditis which preceded them. Now, otitis media and the other complications are frequently met with nowadays in general practice as a complication of sore-throat. Any of these complications may occur singly, or in conjunction in the same patient as the result of an attack of "influenza" or tonsillitis, and I would suggest that in Mr. Owen's case the mastoiditis and the other complications were not in the nature of cause and effect but were all manifestations of an infection entering the system probably via the throat.

[1] Quoted from the Annual Reports of the Chief Medical Officer, Ministry of Health, 1923 (p. 37), 1924 (p. 37), 1925 (p. 38), 1926 (p. 39).

Mr. Owen, indeed, though claiming that the "septic focus" was in the mastoid, yet, in the course of his description of hæmorrhagic mastoiditis, admits himself that "the disease itself is a systemic infection," which amounts to much the same thing as my suggestion.

I am prompted in my comment by the fact that early in 1926 I saw a young man who, during an epidemic of tonsillitis, was taken ill with the latter. Complications in order were otitis media, nephritis, aseptic pulmonary infarction, and peripheral thrombosis. There was also profound anæmia in my case—the man looked as if he had had a severe internal hæmorrhage—which I attributed to a hæmolytic streptococcus. He got well without any operative procedures and is well 23 months later. At the time I had other cases with pulmonary infarction and nephritis which had followed on tonsillitis and influenza; none of these latter had otitis media.

Six months previously to seeing the above case I saw a woman who after influenza and tonsillitis had, like the man described above, nephritis and pulmonary infarction, but not otitis. Other cases of nephritis of similar nature were seen the same week; not one of these had otitis. Arthritis and empyema I have seen follow tonsillitis. Otitis media is such a common complication of these sore-throats that it is not to be wondered if one sometimes sees it in conjunction with the other complications as in the man described above. Mr. Owen says very little about the previous history of his patient; whether, as is highly probable, she had had tonsillitis. There is no mention as to whether a swab of the throat was taken.

The failure of the operative procedures adopted in Mr. Owen's case to stay the march of the blood infection is to be explained, not by the incompleteness of the operative measures, but by the probability that the germs were entering the circulation not via the mastoid but via the upper air passages—a region where, in these days of endemic influenza, many mysterious infections of the body have their origin.

I am, Sir, yours faithfully,

Aberdare, Jan. 7th, 1928. AMBROSE W. OWEN.

VESALIUS AND THE INQUISITION MYTH.

To the Editor of THE LANCET.

SIR,—In the very interesting lecture reported in THE LANCET of Nov. 12th, 1927, Sir Farquhar Buzzard raises many contentious issues. He commits himself to the statement that "Vesalius . . . was condemned by the Inquisition as a sorcerer." The phrase is introduced almost as an obiter dictum, something which everyone knows and need only be mentioned in passing. But what are the actual facts? The whole story stands or falls by a single document; an excerpt from a letter alleged to have been written by Herbert Languetus in Paris to Caspar Peucer in Wittenberg on Jan. 1st, 1565. This excerpt runs as follows :—

> There is a rumour that Vesalius is dead. No doubt you heard that he had gone on a journey to Jerusalem, but I have had a letter from Spain that the cause of his pilgrimage was of a remarkable nature. A Spanish grandee had been treated by him, and upon the death of the patient Vesalius, because of his uncertainty as to the nature of the malady, asked the relatives' permission to open the body. The request was granted, but on opening the body the heart was found to be still beating. Thereupon the relatives, not content with accusing him of murder, denounced him also to the Inquisition on the score of impiety, to the end that their vengeance might be more complete. Since the facts of the case were undisputed the mistake of the great physician could not easily be excused, and the Inquisition was so set on punishing him that the authority and even the prayers of the king could scarce avert the danger. At length, however, in deference to the supplications of the king and of the whole court, he was pardoned on condition that he should expiate his crime by making a pilgrimage to Jerusalem and Mount Sion.

Before considering the above excerpt a few dates will be useful. Vesalius left Madrid early in March, 1564. As he intended to live for the future in Brussels, his wife, family, and furniture accompanied him in

his overland journey to the north-eastern frontier of Spain. In the south of France he parted from the cavalcade, the rest passing on to Belgium while he directed his course to Venice, which he reached about the end of April. Early in May he sailed for the Holy Land. There is no information thereafter till the beginning of December, when some of his fellow pilgrims returning to Belgium brought word that he had died at Zante on Oct. 15th. It might well be, therefore, that the rumour of his death did not reach Paris till the end of December.

From all this, however, it will be evident that the facts alleged to have been written to Peucer must have happened at least nine months before. We may pass over obvious difficulties in the story; that Vesalius was not likely to mistake a living body for one that was dead; that even had he made the mistake the jurisdiction lay with the ordinary courts and not with the Inquisition. But accepting the story as it stands, its remarkable nature, the large number of persons who knew of it (the whole court at least), the unenviable reputation of the Inquisition itself—it is very difficult to understand that not a hint of the drama was heard till Jan. 1st, 1565, probably a year after its occurrence. It may, of course, be urged that the argument from silence is not very convincing, and that after all a year is not a long time. But the argument from silence does not depend in this case on one year, but on 56 years, for the story was not heard of till 1620, when the excerpt translated above was printed by Melchior Adam in his *Vitae Illustrium Medicorum*. This long silence is surely convincing even apart from the events that crowded that half century. Languetus was the representative of the Elector of Saxony, the head of Protestant Europe, to whom any tale against the Inquisition would be welcome. Languetus was a copious correspondent; volumes of his letters, diplomatic and private, have been published. There is one to Mordeisen on the very day (Jan. 1st, 1565), long and chatty, but neither in it or anywhere else is to be found Adam's excerpt, which was printed 39 years after his death. Peucer, too, was bound to have repeated the story if the excerpt ever reached him. After the death of his father-in-law, Melanchthon, he continued the latter's work as the centre of correspondence for the various Reformers, but to none of them did he re-tell the tale. The polemic of that period was fierce to a degree that few moderns can conceive. The Inquisition was loathed by Protestants, especially in the low countries, where the personal friends of Vesalius lived. His widow married again, and the brother of her second husband was a devoted partisan of William of Orange. The Inquisition in Spain courted publicity in regard to its punishments and was no respecter of persons; the Archbishop of Toledo, the Primate of Spain, was during this time its prisoner.

Nor was it that Vesalius had slipped out of public mind. Protestant Europe had ceased to believe in the efficacy of pilgrimages and so refused to think that others could act from such a motive. Thus, while it was agreed that a pilgrimage was the ostensible object of the journey, search was made for a hidden reason. So we find it variously stated: (1) that he wanted to study drugs in the East; (2) that he was tired of court life; (3) that in this way he anticipated his dismissal by Philip; (4) that it was to win a bet; (5) that it was to get away from a nagging wife, &c. None of these writers would have required to make a guess if they had heard about the Inquisition. The history of this tribunal has been told at length, and neither Llorente nor Lea can be said to be biased in its favour. Long lists of its real and supposed victims have been drawn out, but the name of Vesalius does not figure therein.

This long universal silence in regard to an event which from so many different points of view clamoured for record and comment can have only one explanation—viz., that it did not take place, and that the excerpt given by Adam is a forgery. It still finds its way into works of reference—e.g., the eleventh edition of the Encyclopædia Britannica—because these books usually copy from one another. It really owed its life to Boerhaave and Albinus, who gave it in their introduction to the Opera Omnia of Vesalius, published by them in 1725. The undoubted merit of this edition gained it widespread popularity, and so the story came to be generally accepted, especially perhaps because of the long and solemn comment they make on it, beginning—

Atque ita tandem dira sacerdotum tyrannis horribi mortis genere Virum sustulit, cui parem nulla tulerun secula, cujus memoriae grata assurget medicina, quamdi sibi curae erit sua cuique sanitas.

It is only fair to add that the most competen authorities on Vesalius—e.g., Burggraeve, Wauter and Roth—dismiss the story as fantastic.

I am, Sir, yours faithfully,

Edinburgh, Dec. 27th, 1927. G. MATHESON CULLEN.

THE PREVENTION OF DIPHTHERIA.

To the Editor of THE LANCET.

SIR,—During the year which has just passed rath more than 1800 cases have been sent into this hospit with a diagnosis of diphtheria. Admittedly, a co siderable proportion of the total were either exampl of other conditions or of so-called "bacteriologic diphtheria"—the diagnosis having been based up the result of a morphological examination of a cultu from a swab and not upon clinical evidence of t disease. With one exception the staff—medic officers, nurses, and maids—concerned in the trea ment of these 1800 cases was known to be immune i.e., Schick-negative to diphtheria. The members the staff had either been found to be Schick-negati on joining or had been rendered so by means toxoid-antitoxin before being allowed to work in about diphtheria wards. The exception, a marked Schick-positive medical officer, elected to "risk it —and contracted clinical diphtheria. Otherwi there has been no single case of diphtheria amon any section of the staff for the past 12 months. Dr. Burton points out in your issue of Jan. 7 the paper for which I was jointly responsible, and which Dr. Rowland alluded, closed, as it in fa opened, upon the note of active immunisation agai diphtheria. Tonsillectomy in the case of the carr of *virulent* diphtheria bacilli was advocated "u the active immunisation of non-immunes is adopted England upon an adequate scale."

I am, Sir, yours faithfully,

E. H. R. HARRIES,
Medical Superintendent, Birmingham City
Jan. 7th, 1928. Hospitals.

TENTERDEN PARATYPHOID EPIDEMIC.

To the Editor of THE LANCET.

SIR,—I have read with interest the leading art in your issue of Dec. 31st, 1927, upon the prevent of paratyphoid. Of the 53 cases notified in connex with the Tenterden epidemic, we found that 43 83 per cent.) had had milk from the creamery to wh the Watermill Farm supply was sold wholesale. fully agree with your remarks with regard to difficulty of obtaining a satisfactory water-sup at outlying farms, both of the quality and quan required for the scrupulous cleanliness which sho appertain to a good cowshed and dairy. The fa in question is an example, the owner cannot aff the cost of laying on company water to his farm has decided to give up milk production. This unfortunate, and shows the difficulty health offic are confronted with; when the Dairy and Cows Orders are strictly enforced the small farmer is dri out of the milk production business, and the alre too small supply of milk available for the consum is lessened. It is not always easy to condemn a at sight. In a village in the South-West Kent recently we had paratyphoid occur. The chem analysis of the well showed the water to be of "i organic quality." As company water was rea available I recommended that the well should

closed. The rural district council decided accordingly, but this decision was reversed by the magistrates on appeal from the parish council.

With regard to milk production, what regulations cannot accomplish education, we hope, will. In this county, clean milk competitions, which are organised by the Kent County education and agriculture committees conjointly, are proving very successful. Some small farmers who had almost been frightened out of the milk business by the new Government dairy regulations have now, after a course of instruction on clean milk production, decided to carry on. In several cases, in spite of somewhat primitive equipment and none too structurally satisfactory cowsheds, a milk of a high standard of cleanliness is being produced.

In your remarks on the Tenterden epidemic you do not comment on the necessity of early Widal tests being made upon cases of doubtful illness occurring on dairy farms. The patients at Watermill Farm had been seen by three medical practitioners and the agreed diagnosis was "bacillus coli infection." Though the first case was seen on July 5th it was not till August 11th, the second day of the epidemic, that Widal tests were taken by the medical attendant on the recommendation of the medical officer of health; all the tests were positive. We had stopped the milk-supply on August 10th.

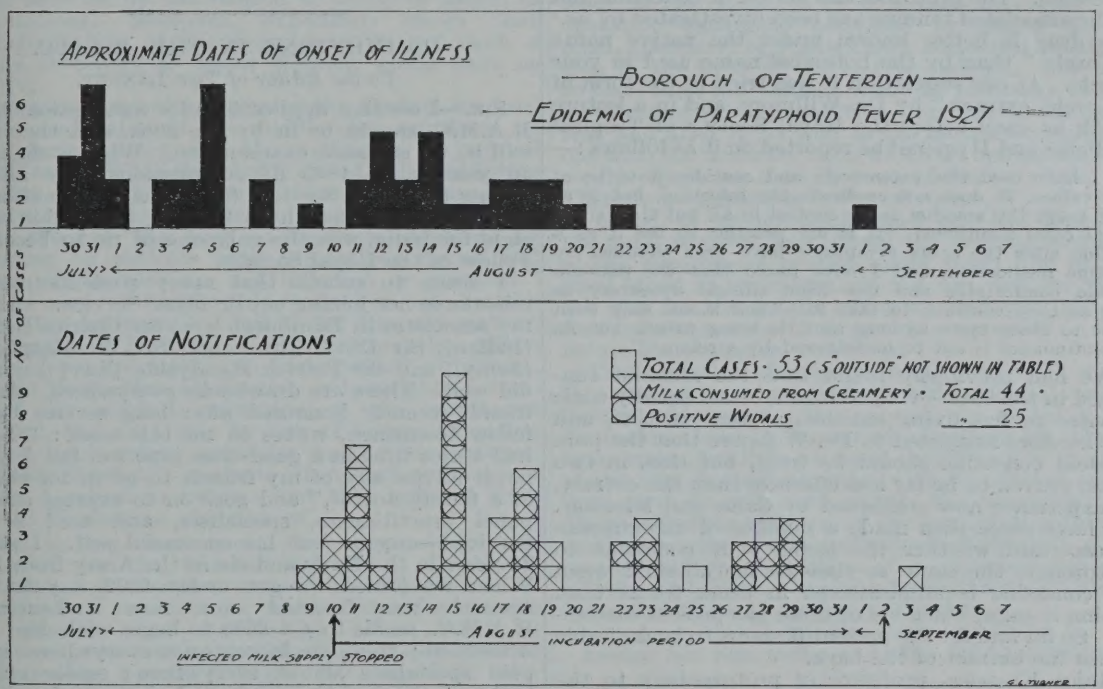
The conclusions I gave in my report upon the epidemic, together with the reproduction of the graph I had prepared, may be of interest. This shows very clearly how the cases ceased within the typhoid incubation period of 5 to 23 days from the date the milk-supply from the farm was stopped. An epidemic such as this makes one appreciate the ready facilities provided at the county laboratory by Dr. A. Greenwood. Previously I did not advocate the pasteurisation of milk because of the consequent lessening of the vitamin content. Now this epidemic has convinced me of the necessity of pasteurisation every time. I note that the large dairy combines, even with their careful methods of production, consider this a necessity; much more is it so in the case of the small producer and distributor.

It is satisfactory and greatly to the credit of the doctors and nurses dealing with the cases treated at home and in the hospitals that there were no fatal cases.

Three important lessons are to be learned from this epidemic:—

(1) I consider that, in view of the ever-present possibility of milk being a vehicle for the spread of infectious disease, medical practitioners should treat any illnesses occurring on dairy farms and premises with great care. In fact, it might be advisable to treat any cases of illness on such farms as infectious diseases until it is definitely proved that they are not. It is also advisable for doctors to make ready use of the facilities offered by the county laboratories.

(2) Whilst recognising the considerable advance made in the production and sale of milk with regard to cleanliness and handling, persons engaged in this business cannot be too careful. To obtain a perfect milk-supply is not a matter of palatial cowsheds, but is from first to last a matter of education in what one might describe as "surgical" cleanliness. Perhaps it is too ideal to expect the aseptic cleanliness of the hospital; nevertheless, if milk is to be considered safe for infants and invalids in particular, dairy and farm cleanliness must be of a much higher standard than it is at present.



An absolute essential of reasonable dairy cleanliness is, of course, a plentiful and pure water-supply. Meantime, in my opinion, the only safety lies in commercial, or failing that, domestic pasteurisation. I would just add that to destroy all organisms, including typhoid and tubercle bacilli, in milk, this should be retained at a temperature of not less than 145° and not more than 150° F. for at least half an hour, and be immediately cooled to a temperature of not more than 55° F. This means a little trouble, but better that than the great trouble and inconvenience, to say the least of it, of an epidemic such as has been experienced in the borough of Tenterden.

(3) A very important business matter arose in connexion with this epidemic, which resulted in the County Court case of "Clarke *v.* Jefferies," heard by Judge Moore Cann at Eastbourne. At this case the medical officer of health and the sanitary inspector were subpœnaed to attend and give evidence. It appears that Jefferies was negotiating for the sale of "Ye Olde Creamery" dairy business at Tenterden on August 7th, and that when the epidemic broke out on the 10th the purchaser refused to complete, and sued the vendor for the return of the deposit money. Apart from the public health standpoint, with which we only are concerned, no further comment is required to emphasise the necessity of all persons engaged in the production and distribution of milk taking every possible step in their commercial methods to prevent such an occurrence in the future.

As health officials we do not wish to discourage milk production, but the reverse; the people, and especially the children, do not drink enough milk.

We support the dairy trade's slogan, "Drink more milk," but it must be clean milk and guaranteed to be free of all contamination or infection.

I am, Sir, yours faithfully,

S. NICOL GALBRAITH,
Medical Officer of Health, S.W. Kent Health Area.

Tonbridge, Jan. 2nd, 1928.

AN INDIAN REMEDY AGAINST DYSENTERY.

To the Editor of THE LANCET.

SIR,—The information given in your annotation last week (p. 38) on an Indian remedy against dysentery can be usefully supplemented by experience of *Holarrhena antidysenterica* bark in this country. Burn[1] gave an account of the physiological action of conessine, holarrhenine, and oxyconessine, and Pyman[2] described the chemical properties of holarrhenine and conessine. The protozoocidal action of conessine and of the associated tannins has been investigated by us.[3] The drug is better known under the native name "Kurchi" than by the botanical name used in your article. At our suggestion it was tried in the form of "Kurchi extract" by Dr. Willmore, and in a lecture which he gave before the Royal Society of Tropical Medicine and Hygiene[4] he reported on it as follows:—

"I have used this extensively and consider it to be of real value. It does not eradicate the infection, but it at least keeps the amœbæ under control in all but the exceptional cases mentioned. It is my practice to use it as a routine after the acute symptoms have been subdued by emetine medication, and I have found that the patients remain comfortable and free from clinical dysentery as long as they continue to take it. Their stools may even cease to show cysts as long as it is being taken, but its discontinuance is apt to be followed by a relapse."

We had previously found that the alkaloid contained in the bark—viz., conessine—was equally toxic in vitro to free-living amœbæ, as was emetine, and we therefore suggested to Dr. Willmore that the pure alkaloid conessine should be tried, but this, in two cases, proved to be far less effective than the extract, an experience now confirmed by Caius and Mhaskar. We have since then made a number of experiments to ascertain whether the toxicity of conessine to protozoa is the same as that of the alkaloid when the conessine is administered in other forms than as simple salts, but none of these has proved successful. So far and for the present it seems to be desirable to use the extract of the bark.

Major Knowles, professor of protozoology to the Calcutta School of Tropical Medicine, who has done a great deal of work on this subject in India during the last two years, finds the extract satisfactory, and, as it can be administered in compressed form, it avoids the serious difficulties presented by the modes of administration suggested by the authorities quoted in your article, which involve the daily ingestion of several fluid ounces of a peculiarly nauseating decoction of the bark or a quarter of an ounce of an equally unpleasant dry powdered bark, methods perhaps possible with patients in the Middle Ages, but hardly feasible to-day, except perhaps with primitive peoples who like their medicine to taste "strong." Major Knowles, as the result of the treatment of two cases of amœbic dysentery with Kurchi extract in solid form, states[5] that in both cases the dose was tolerated very well, the amœbic infection appeared to be eradicated, and cure was apparently both rapid and complete. The same author[6] after several years' experience with this drug states: "On the other hand, it is doubtful whether emetine alone will ever entirely eradicate an infection with *E. histolytica*, and its use requires to be supplemented by the use of such a drug—e.g., as Kurchi."

[5] Ann. Report Calcutta School of Trop. Med., 1924, p. 70.
[6] An Introduction to Medical Protozoology, 1928, p. 93.

It is perhaps also of interest to mention that in a recent paper on the chemistry of conessine Dr. J. L. Simonsen mentions[7] that he had to give up work on the alkaloid owing to a severe attack of giant urticaria, probably caused by certain derivatives of the alkaloid. This appears to be the first recorded instance of the kind, although a considerable number of chemists have worked with conessine. It is, however, possible that the real cause of the attack in Dr. Simonsen's case was the methyl iodide, used in the process of "exhaustive methylation" which he applied to the alkaloid. Experience in these laboratories shows that some people possess skins highly susceptible to the action of methyl iodide.

We are, Sir, yours faithfully,

T. A. HENRY,
Director, Wellcome Chemical Research Laboratories.

H. C. BROWN,
Wellcome Bureau of Scientific Research

Jan. 9th, 1928.

COMMISSIONS IN THE R.A.M.C.

To the Editor of THE LANCET.

SIR,—I see that applications for commissions in the R.A.M.C. should be in by the 20th, and that there will be no entrance examination. What a change in 40 years! In 1885 64 commissions were allotted among the three Services (the same examination for all), and the sixteenth on the list, the junior of the eight for India, was the only one of us to become a Fellow of the Royal Society.

I desire to submit that many students make a mistake in not joining one or other Service. Among my associates in Edinburgh were Sir Charles Bedford (Indian), Sir David Bruce and Sir W. Macpherson (Army), and Sir Patrick Handyside (Navy), who all did well. There are drawbacks everywhere. An old friend, recently honoured after long service by his fellow townsmen, writes to me this week: "I have had a nice time in a good-class practice, but I would never advise any of my friends to go in for the life of a family doctor," and goes on to express envy of panel practitioners, specialists, and me! in the Service!—anyone but his successful self. I served 26 years in the Navy and six in the Army from 1916. When we joined we got under £200 a year, and research was frowned on; now a lieutenant, R.A.M.C., seems to get £500 to begin with, and £570 if married; there are laboratories everywhere, extra-paid specialists almost everywhere; senior officers, better trained and encouraged, have a far better position, while the juniors (the talk is this week of the R.A.M.C.) have the Millbank mess to stay in if they are in London on leave, where they meet other officers of the Corps, especially the research workers, and have the run of the fine library. I am glad to say a young officer told me recently he had joined the Corps because he had heard me lay out to the Royal Medical Society the advantages of the Services. They offer great fields for research to capable officers, especially the Indian Service which has so much disease to treat. Practice improves output in science as in games, so that Service has produced in my time Ross, Bedford, Bannerman, Freyer, Rogers, Carter, Elliott, McCarrison, to name a few, and though juniors regret some conditions, their difficulties will hamper less the tougher men. A temporary officer, like myself, in 1922 applied to join the R.A.M.C. "Why?" said his colonel. "Well," he said, "I suppose it is because I want to see the world on the cheap." Not a bad reason, but there are others.

One caution should be given. We joined with less than £200 a year and a promise, after 20 years, of a £365 pension; wealth it seemed beyond the dreams of avarice. They start at £500, still with only the same £365 ahead. They must save or else insure.

I am, Sir, yours faithfully,

W. E. HOME,
Fleet Surgeon, R.N., and Major, R.A.M.C.

Piccadilly, W., Jan. 7th, 1928.

[7] Jour. Chem. Soc., 1926, p. 2124.

AN OPERATION FOR THE ALLEVIATION OF DEAFNESS.

To the Editor of THE LANCET.

SIR,—Major Nesfield claims that the operation for the alleviation of deafness which he describes is not only simple but also satisfactory. The idea of opening up the middle ear by a new route in cases of severe Eustachian obstruction when the tube fails to function is by no means original. As an experimental procedure it was tried many years ago, by myself amongst others, with such discouraging results as to have long ago been abandoned. Apart from pathological considerations, the practical difficulty of maintaining a patent channel to the posterior end of the middle ear cleft is such that in the great majority of cases the middle ear proper becomes again shut off by contraction of tissue or fusion of granulations. Moreover, experience shows that epithelialisation of the bony tract is not such a simple procedure as Major Nesfield would have us believe.

The physiological function of the Eustachian tube is the ventilation of the middle ear, ventilated as it is during every act of swallowing in normal individuals. When chronically closed, this ventilating function is in abeyance with consequent damage to the contents of the tympanum. Major Nesfield states: "My attempt has been to alleviate deafness by operating on patients with normal ear drums and whose middle ears are not inflamed or purulent." Also he says: "I make this channel on ears healthy except for deafness." I fail to see how any patient with marked Eustachian obstruction, the raison d'être of his operation, can have normal ear drums. Chronic Eustachian obstruction is invariably accompanied by marked retraction of the membrana tympani, and as a rule by loss of lustre, alteration of the light reflex, ossicular and other changes. If Major Nesfield's patients then had normal ear drums, I refuse to believe that they suffered from chronic Eustachian obstruction.

Nor, in my experience, does any middle ear, subjected to the baneful influences of chronic Eustachian obstruction, escape the consequences of inflammatory reaction, as ocular inspection reveals and clinical tests demonstrate. How such an operative procedure as described by Major Nesfield can possibly benefit patients suffering from otosclerosis, a disease of the labyrinthine segment of the ear, and where the Eustachian tube is as a rule somewhat dilated, I also fail to understand. All recognised authority is, and for long has been, against operative procedures in this particular type of deafness. It seems to me incredible that any child of the age of 4 years should require such drastic interference.—I am, Sir, yours faithfully,

Manchester, Jan. 10th, 1928. WILLIAM MILLIGAN.

To the Editor of THE LANCET.

SIR,—I agree with Major Nesfield's remarks in your last issue, where he points the distinction between the operation he advises for the alleviation of deafness in non-suppurative ear disease and that advocated by Mr. Charles Heath for aural suppuration; the latter's panegyric on his results is therefore out of place in this discussion. While Mr. Nesfield states that the best results are obtained by this operation where the deafness is due to blocking of the Eustachian tubes with indrawn ear-drums, he also mentions that he has operated on many cases of otosclerosis. The pathology of these two conditions is entirely distinct, and it is difficult to understand in what way opening the antrum can benefit otosclerosis. If progress is to be made with any method of treatment, it is essential that the various types of deafness be carefully differentiated beforehand. Dr. Hill's suggestion that Mr. Nesfield should endeavour to obtain the collaboration of an experienced otologist is a good one.

That Mr. Nesfield finds it difficult to keep open the communication between the antrum and the external auditory meatus is shown by the fact that, in the only three patients I have examined after he had operated, this was closed, not by a thin membrane, but by a thick layer of tissue, the only indication that an opening had been made being a slight depression on the posterior meatal wall.

I am, Sir, yours faithfully,

London, W., Jan. 6th, 1928. HAROLD BARWELL.

To the Editor of THE LANCET.

SIR,—Those whose views have got stabilised as the result of prolonged experience have to beware lest they get fossilised, and they do well to give a patient and, primarily, a favourable consideration to any new methods, however opposed they may seem, at first sight, to those already in vogue. The operative treatment described by Major Nesfield must, therefore, be studied with respectful consideration in the light of the results claimed. For these to have their full value it would be necessary to have a statement of the condition previous to the operation and after it, as well as the ultimate results, set out with the accuracy with which an ophthalmologist would report the data in cases of disease of the eye. There is no objection to the intrusion, if such it can be called, of an ophthalmologist into the domain of the aural surgeon, and indeed the delicate technique of the experienced oculist would stand him in very good stead in operating on the ear, but we would ask him for the details which an otologist, bringing forward a new operation, would be expected to place before his otological confrères.

The formation of a fistula in the bony back wall of the meatus is a proceeding which should not be lightly undertaken. It can only be called a new Eustachian tube in respect of admitting air into the tympanum, but it has none of the protective qualities of the true Eustachian tube, with its ciliated epithelium and its advanced guard, the nasal passages. There is further a chance of the immigration into the mastoid cavity of the epithelium of the skin of the meatus and the formation of a cholesteatoma with all its possibilities. Looking forward with interest to the publication of further particulars,

I am, Sir, yours faithfully,

London, Jan. 10th, 1928. JAMES DUNDAS-GRANT.

To the Editor of THE LANCET.

SIR,—I am astonished that the very interesting article by Major Nesfield has attracted so little attention. Now that a claim is made that by a simple routine operation these hopeless cases of chronic deafness can be cured, the claimant must not be surprised if he meets with blank incredulity, which can only be removed by the exhibition of patients or by the publishing of detailed figures "before and after." The recent book by Dr. Cathcart on the Electrophonoïde is a model in this respect, as a complete table of figures is given. My own experiments in this direction have not had the results claimed by Major Nesfield, but many attempts must have been made by others, and further information would be useful to those who think that the permanent ventilation of the middle ear either via tympanic membrane or antrum will ultimately solve the problem of chronic middle-ear deafness.

I am, Sir, yours faithfully,

Manchester, Jan. 9th, 1928. WILLIAM WILSON.

CONFERENCE ON SILICOSIS.—Mr. H. B. Butler, deputy director of the International Bureau at Geneva, in a recent address at Pretoria, said that there was reason to hope that a conference on silicosis would in the near future be held in Johannesburg. Supporting his proposal, Sir Spencer Lister, director of the South African Institute for Medical Research, said that in no place in the world was silicosis more prevalent than in Johannesburg, and nowhere was there so efficient an organisation for treating the disease.

Obituary.

ALEXANDER CAMERON MILLER, M.D., F.R.S. EDIN.

Alexander Cameron Miller, of Fort William, whose death occurred on the last day of the old year, was one of the most distinguished practitioners in Scotland; he was both a great rural doctor and a great public servant. Born at Fort William in 1861, he graduated M.B., C.M., at Edinburgh University in 1883, proceeding to the M.D. (with honours) in 1888. For over forty years he carried on practice from the centre in his native town over a large Highland area, where mountains and lochs were permanent obstacles to travel, while flooded rivers were more than occasional. He was poor-law medical officer for the parishes of Ardgour and Kilmallie, and for part of Kilmonivaig; the difficulties of the medical life with patients separated in glens by distances rising to 50 miles and more can be surmised even by those with no personal knowledge, and one of the most romantic documents in connexion with medical practice ever indited was Miller's account of how, to attend two isolated patients, he crossed the flooded river Spean in a bath—the only method of transit. He was also medical officer of health for Fort William and for the county district of Lochaber, and was from the foundation medical superintendent and surgeon of the Belford Hospital, an institution of some twenty beds. With a large private practice he was widely recognised as a consultant. On the public health and poor-law side he was well known for the reliability of his work to three central authorities in succession—the Board of Supervision, the Local Government Board for Scotland, which superseded that Board in 1894, and to the Scottish Board of Health, which in 1919 incorporated in one the Local Government Board and the Scottish Insurance Commission.

With the passage of the National Insurance Acts his work became even harder. In 1912 he was made a member of the departmental committee (the Dewar Committee) set up by Mr. Lloyd George to inquire into medical service, including nursing, in the Highlands and Islands, with Sir John Dewar, now Lord Forteviot, as chairman. The report of this body is one of the most important documents in Scottish medical history, and Miller impressed all the workers on it by his professional insight and range of his knowledge. His work on the Dewar Committee was of the highest value; for he had an unsurpassed knowledge of all the medical problems in the district, and the Board owed much to his sagacity at the discussions. The Scottish Board of Health appointed him to the Highlands and Islands Consultative Council, where his widely based judgments always carried weight.

He was a natural scholar, at home in Gaelic, and having travelled much on the continent knew two foreign languages well, while maintaining his interest in classical literature. He wrote, as might be expected, thoroughly well; his private letters were often long and brilliant, and to the Carnegie U.K. report on "Scottish Mothers and Children" he contributed a "regional study" that will remain one of the classical social accounts of a Scottish medical practice for a period of 30 years, for he showed system in his records and elegance in literary expression.

For his war services he earned prompt promotion to a lieutenant-colonelcy, and here again his genial qualities and intimate knowledge of men served him well. For it is not given to everyone, however kind and sympathetic, to identify himself in the way that Miller could with his humbler fellow-men. "Once, in Harris," an intimate friend of Miller writes to us, "I heard him in a weaver's 'black-house' sustain his part in a spinning song, the spinners and he responding to each other perfectly and with similar artistic feeling." Such men make good recruiting officers as well as good colonels and good doctors.

The funeral, which took place at Fort William on Jan. 4th, was one of the largest ever witnessed at Lochaber; the cortège extended the whole length of the street, and was made up of official representatives and social magnates, who mingled with farmers, crofters, and shepherds from distant glens assembled to do honour to a dead friend.

Medical News.

UNIVERSITY OF LONDON.—At recent examinations the following candidates were successful:—

M.D.

Branch I., Medicine.—Enid A. Ceiriog-Cadle, London Sch. of Med. for Women; Gwendolen C. Cotton, London Sch. of Med. for Women; William Evans, London Hosp.; Una C. Garvin, London Sch. of Med. for Women; Alice M. C. Macpherson, London Sch. of Med. for Women; Alan C. T. Perkins, King's College Hosp.; Evelyn N. Popper, London Sch. of Med. for Women; Thomas W. Preston, King's College Hosp.; William G. Sears, Guy's Hosp.; Harvie K. Snell, King's College Hosp.

Branch III., Psychological Medicine.—Isaac Atkin, St. Bart.'s Hosp.; Florence M. Gamble, London Sch. of Med. for Women.

Branch IV., Midwifery and Diseases of Women.—Richard A. Brews, London Hosp.; Dorothea A. C. Hunt, London Sch. of Med. for Women; R. G. Maliphant, University College Hosp.

University College.—A course of five public lectures by Dr. R. J. Ludford on Cytology in Relation to Physiological Processes will be given on Jan. 19th and 26th, and Feb. 2nd, 9th, and 16th, at 5.30 P.M.—A course of ten lectures on Comparative Physiology, to be given by Mr. C. F. A. Pantin, will begin to-day (Friday), Jan. 13th, at 5 P.M., and continue at the same hour on Fridays until March 16th.—Prof. A. V. Hill, F.R.S., will give six lectures on Muscle, at 4 P.M. on Wednesdays, from Jan. 18th to Feb. 22nd inclusive.

King's College.—At 5 P.M. on Tuesdays, from Jan. 17th to March 6th, inclusive, Mr. J. A. Hewitt, D.Sc., will lecture on Integration in the Nervous System.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The following lectures have been arranged: Jan. 16th, 18th, 20th, 23rd, 25th, 27th, Prof. Sir Arthur Keith on Factors Concerned in the Growth of the Human Body; Jan. 30th, Mr. W. E. M. Wardill on Certain Aspects of Cleft Palate, with Observations on the Causes of Defective Speech and the Remedies proposed for their Treatment; Feb. 1st, Mr. H. S. Souttar on New Methods of Surgical Access to the Brain; Feb. 3rd, Mr. E. Miles Atkinson on the Pathology, Diagnosis, and Treatment of Abscess of the Brain; Feb. 6th, Sir Percy Sargent on the Surgery of the Posterior Cranial Fossa; Feb. 8th, Prof. G. Grey Turner on the Treatment of Congenital Defects of the Bladder and Urethra by implantation of the Ureters into the Bowel, with a record of 14 personal cases; Feb. 10th, Dr. J. H. Sheldon on an Undescribed Disease of Bone; Feb. 13th, Dr. Adolphe Abrahams on the Physiology of Violent Exercise in relation to the Possibility of Strain; Feb. 15th, Mr. Alexander Fleming on Lysozyme, a Bacteriolytic Ferment normally present in Tissues and Secretions; Feb. 17th, Miss Ida C. Mann on the Regional Differentiation of the Vertebrate Retina; Feb. 20th, Mr. C. E. Shattock on Pathological Specimens in the Museum; Feb. 22nd, Mr. C. P. G. Wakeley on Investigations into the Surgical Diseases of the Salivary Glands, including their Pathology and Treatment; Feb. 24th, Dr. W. D. Newcomb on the Relationship between Peptic Ulceration and Gastric Carcinoma.

BETHLEM ROYAL HOSPITAL.—A course of lectures and practical instruction for the Diploma in Psychological Medicine of various universities will be given at this hospital, beginning on Jan. 16th. Particulars may be had from the Physician-Superintendent.

LANCASTER ISOLATION HOSPITAL.—During the flood on the night of Oct. 28th last this hospital was partly submerged, and three sanatorium patients were drowned in their beds. Lancaster town council is now applying to the Ministry of Health for permission to erect a new isolation hospital on a better site, and it is hoped that the Lancashire County Council, Morecambe corporation, and the district councils of Carnforth and Lunesdale will contribute to the cost of a central scheme. It is proposed to include a block of buildings capable of accommodating 30 patients for use as a tuberculosis sanatorium by the county council.

ORDER OF ST. JOHN OF JERUSALEM.—Among recent appointments to the Order of the Hospital of St. John of Jerusalem are the following:—Commanders: Major-General John Taylor Fotheringham, Colonel Sir Edward Newbury Thornton, and Colonel Charles Pye Oliver. Officers: Dr. Wilfred Vincent Miller Koch, Mr. Harold Branson Butler, M.B.E., Sir John Atkins, and Dr. James Carter Ogilvie.

DONATIONS AND BEQUESTS.—Mr. John Whewell Simpson, of Fieldside, Keswick, Cumberland, late of Royton, Lancashire, has bequeathed £40,000 to the Manchester Royal Infirmary and £1000 each to Dr. Barnardo's Homes, and to St. Dunstan's Hostel for Blinded Sailors and Soldiers. The bequest to the Manchester Infirmary is the largest ever made to this institution.—Mr. Alfred Cockerill, of Abington, Northampton, left £1000 to Northampton General Hospital, as a "Cockerill Bequest" for or towards the upkeep of a bed there; £750 to the Manfield Orthopædic Hospital, and £500 to the Home for Incurables, Leamington.

BRITISH EMPIRE CANCER CAMPAIGN.—At a quarterly meeting of the Grand Council held on Jan. 10th it was announced that a trust fund had been created by the executors of the late Mr. William Johnston, of Liverpool, to be known as the Aileen Congreve Memorial Fund. Of more than £18,000 available £16,000 will become a permanent trust, whose interest will be used for cancer research in Liverpool. It was also stated that an anonymous donation of £10,000 had been received by the campaign, and that the interest on this would be available for general research work. The sum of £3000 was granted for maintenance of the cancer research laboratories of the Middlesex Hospital, and a further sum of £900 for the year's maintenance of the special radiological research department there. A grant of £600 to the Cancer Research Committee of the London Association of the Medical Women's Federation was renewed for the ensuing year. An announcement was made about the International Convention on Cancer Research to be held in London in July. Particulars of this will be found in an editorial column.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Monday, Jan. 16th, at 5 P.M., at the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, Sir James Purves-Stewart will lecture on Acute Drunkenness. On Thursday, Jan. 19th, at 3 P.M., at the Royal Eye Hospital, St. George's-circus, Mr. Letchworth will give a clinical demonstration. The lecture and the demonstration are open to members of the medical profession without fee. The following week there will be a lecture and surgical, medical, and ophthalmic demonstrations. A special course in cardiology will be given at the National Hospital for Diseases of the Heart, Westmoreland-street, commencing on Monday, Jan. 16th, for a fortnight, from 10 A.M. to 4 P.M (entries limited to 20). A course of eight lecture-demonstrations on Psychological Medicine will be given at the Bethlem Royal Hospital, on Tuesdays and Saturdays, at 11 A.M., commencing on Jan. 17th. During February, for a fortnight, a whole-day course in Diseases of Children will be held at the Paddington Green Children's Hospital and the Victoria Hospital for Children; during the afternoons and evenings, for four weeks, a course in Venereal Diseases will be held at the London Lock Hospital. A course in dermatology will be held every afternoon from Jan. 30th to Feb. 25th, at the St. John's Hospital (practical pathological demonstrations can also be arranged). From Feb. 20th to March 3rd, at the Queen Mary's Hospital, Stratford, a whole-day course will be given in medicine, surgery, and the specialties, consisting of work in the various departments of the hospital. From Jan. 30th to March 23rd, at the National Hospital, Queen-square, a course in Neurology will be given, consisting of clinical and pathological lectures and demonstrations, teaching in the out-patient department, lectures on the anatomy and physiology of the nervous system, and demonstrations on methods of clinical diagnosis in diseases of the nervous system. Information, syllabuses, tickets, and copies of the *Post-Graduate Medical Journal* may be had from the Secretary of the Fellowship, at 1, Wimpole-street, W.

Medical Diary.

SOCIETIES.

ROYAL SOCIETY, Albemarle-street, W.

THURSDAY, Jan. 19th.—4.30 P.M. *The following papers, among others, will be read:* P.H.H. Gray: Formation of Indigotin from Indol by Soil Bacteria. (Communicated by Sir John Russell.) R. A. Fisher: Triplet Children in Great Britain and Ireland. (Communicated by Sir Arthur Keith.) *The following papers will be read in title only:* J. Piiper: On the Evolution of the Vertebral Column in Birds illustrated by its Development in Struthio and Larus. (Communicated by E. W. MacBride.) F. G. Gregory and A. S. Hornè: A Quantitative Study of the Course of Fungal Invasion of the Apple Fruit and its Bearing on the Nature of Disease Resistance. Parts I. and II., and the Differential Effect of the Ions of Three-salt Solutions on the Growth of Potato Plants in Sand Culture. (Communicated by V. H. Blackman.) Sir Kenneth Goadby: Bacterial Proteins. L. Rapkine and R. Wurmser: On Intracellular Oxidation-Reduction Potential. (Communicated by Sir F. Hopkins.) F. W. R. Brambell: Development and Morphology of the Gonads of the Mouse. Part II. (Communicated by J. P. Hill.) R. C. Punnett: Linkage Groups and Chromosome number in *Lathyrus*.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Jan. 16th.—LIBRARY: The main library will close at 5 P.M., but readers will be accommodated in other rooms until 6.30 P.M. 8.30 P.M., SOCIAL EVENING. From 8.30 to 9 P.M. Fellows and guests will be received in the Library by the President and Lady Berry. At 9.15 P.M. Dr. Jane Walker will give an address entitled Saints, Medicine, and Surgery (with illustrations). A number of exhibits, kindly lent by the Wellcome Historical Medical Museum and by Miss Marie Leon will be on view. Music and light refreshments.

TUESDAY.—5.30 P.M., GENERAL MEETING OF FELLOWS. Ballot for election to the Fellowship. 8.30 P.M., PATHOLOGY. Papers, &c.: Prof. J. McIntosh: The Histology of Some Virus Infections of the Central Nervous System. Mr. A. Fleming: The Influence of Temperature on the Agglutination of Bacteria. Dr. F. T. Ridley: A New Mixing Machine.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) 8 P.M., OBSTETRICS. Specimen: Mr. W. Gilliatt: Sarcoma of the Uterus. Short Communication: Prof. J. B. Cleland (University of Adelaide): Difficult Labour in a Pure-blooded Australian Aboriginal Woman. Paper: Mr. G. F. Gibberd: A Consideration of the Results of Albuminuria Occurring during Pregnancy with Special Reference to the Relationship between Pregnancy, Kidney, and Chronic Nephritis. 8.30 P.M., ELECTRO-THERAPEUTICS. Discussion on Diathermy in Relation to Circulatory Disturbances, Particularly in High Blood Pressure, &c. Openers: Prof. Sidney Russ and Dr. T. F. Cotton. Dr. Justina Wilson, Dr. Agnes Savill, and others will also speak.

HUNTERIAN SOCIETY.

MONDAY, Jan. 16th.—9 P.M. (at the Mansion House). Dr. Howard Kelly of Baltimore, U.S.A.: Rubbing and Reasoning.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 11, Chandos-street, Cavendish-square, W.

THURSDAY, Jan. 19th.—8.15 P.M., preceded at 7.45 P.M. by a demonstration, Surgeon-Commander D. H. C. Given, R.N.: Health Organisation on H.M. Naval Base, Singapore, and Results, with comments on the Practice of Preventive Medicine seen during Tours in the Far East (illustrated by lantern slides).

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Upper Montague-street, Russell-square, W.

FRIDAY, Jan. 20th.—5 P.M., Dr. Walter Elliot, M.P., and Prof. R. H. A. Plimmer, D.Sc., on Recent Advances in the Knowledge of Food.

EUGENICS SOCIETY.

THURSDAY, Jan. 19th.—8.30 P.M. (at the Rooms of the Royal Society, Burlington House, W.). Mr. F. C. Bartlett: Innate Qualities in Social Classes. Discussion.

SOCIETY OF SUPERINTENDENTS OF TUBERCULOSIS INSTITUTIONS.

FRIDAY, Jan. 20th.—3 P.M. (at 122, Harley-street, London, W.), annual general meeting. Discussion on Pros and Cons of Tuberculosis Propaganda, to be opened by Dr. W. Brand.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 16th, to SATURDAY, Jan. 21st.—FELLOWSHIP OF MEDICINE. Lecture at Medical Society, 11, Chandos-street, Cavendish-square, W. Mon., at 5 P.M., Sir James Purves-Stewart, K.C.M.G.: Acute Drunkenness. —ROYAL EYE HOSPITAL, St. George's Circus, S.E. Clinical demonstration on Thurs., at 3 P.M., by Mr. Letchworth. The above lecture and demonstration are open to members of the medical profession, without

fee.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E. Course in Psychological Medicine. Lecture-demonstrations on Tues. and Sat. at 11 A.M.—CHILDREN'S CLINIC and other hospitals. Post-graduate course in Diseases of Children, occupying mornings and some afternoons. (Second week.)

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, W.
MONDAY, Jan. 16th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Dr. Trevor Davies: Gynæcological Department. 4.30 P.M., Dr. Carmichael Low: Sprue (lecture).
TUESDAY.—2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients.
WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards.
THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. MacDonald: Genito-urinary Department. 2 P.M., Mr. Bishop Harman: Eye Department.
FRIDAY.—10 A.M., Dr. Pritchard: Special Medical Treatment Clinic. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department. 4.30 P.M., Dr. Archer: Chemical Examination of Blood (lecture-demonstration).
SATURDAY.—10 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Owen: Medical Diseases of Children.
Medical and Surgical Out-patients, Operations, Special Departments, daily, 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 1 P.M.

NORTH-EAST LONDON POST-GRADUATE COLLEGE Prince of Wales's General Hospital, Tottenham.
MONDAY, Jan. 16th.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.
TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Throat, Nose and Ear Clinics. Operations.
WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.
THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, and Ear, Nose and Throat Clinics. Operations.
FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.
TUESDAY, Jan. 17th.—5 P.M., Dr. H. G. Adamson: Erythema Multiforme.
THURSDAY.—5 P.M., Pathology Demonstration.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Grays' Inn-road, W.C.
MONDAY, Jan. 16th.—1.30 P.M., Mr. R. J. Cann: Hearing Tests.
WEDNESDAY.—1.30 P.M., Mr. N. MacKeith: Examination of the Ear.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.
TUESDAY, Jan. 17th.—3.15 P.M., Sir William Willcox: The Clinical Manifestations of Parenteric Infections.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street, W.C.
THURSDAY, Jan. 19th.—4 P.M., Dr. D. Paterson: Digestive Disturbances in Infancy and Their Treatment.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
WEDNESDAY, Jan. 18th.—4.30 P.M., Mr. Rowland Burrows: The Medical Practitioner in Relation to the Administration of Justice.

ST. MARY'S HOSPITALS, MANCHESTER, Whitworth-street West Branch.
FRIDAY, Jan. 20th.—4.30 P.M., Dr. F. H. Lacey: Abortion: Its Prevention and Treatment.

Appointments.

ROBB, J. J., M.B., Ch.B. Edin., F.R.C.S.Edin., has been appointed Surgeon Consultant, Gilbert Bain Hospital, Lerwick.

TIPPETT, G. O., M.B., B.S. Lond., M.R.C.S., Resident Surgical Officer, Wingfield Orthopædic Hospital, Oxford.

Westminster Hospital: SEGAL, S., L.R.C.P. Lond., M.R.C.S., Resident House Physician; ROBOTTOM, P. M., L.R.C.P. Lond., M.R.C.S., and SOUTTER, P. A. M., L.R.C.P. Lond., M.R.C.S., Resident House Surgeons.

Certifying Surgeons under the Factory and Workshop Acts: EDWARDS, L. C. J., L.R.C.P. Lond., M.R.C.S. (Braintree); OLIVER, C. P., Jun., M.B., B.Chir. Camb. (Maidstone); DAVIES, R. W., L.R.C.P. Lond., M.R.C.S. (Rushden); and WARNER, C. H., M.D., B.S. Lond., D.P.H. (Southwell, Notts.).

Vacancies.

For further information refer to the advertisement columns.

Barnsley, Beckett Hospital.—Two Hon S.'s for Out-patients. Also Hon. Asst. Ophth. S.

Bethnal Green Hospital, E.—Asst. M.O. £350.

Birmingham City.—Sen. Asst. M.O.H. £1100.

Blyth, Borough of.—M.O.H., &c. £800.

Brighton, New Sussex Hospital for Women and Children, Windlesham-road.—Hon. Radiologist and Hon. Surg. to Ear, Nose and Throat Dept.

Bristol Royal Hospital for Sick Children and Women.—H.P. £125.

Central London Ophthalmic Hospital, Judd-street, W.C.—Two Out-patient Officers. Each £150. Also Jun. H.S. At rate of £50.

City of London Hospital for Diseases of the Heart, Victoria Park, E.—P. to Out-patients.

Colchester, Essex County Hospital.—H.S. £150–£200.

Coventry, City of.—Deputy M.O. £750.

Croydon County Borough.—Asst. M.O.H., &c. £600.

Durham, Earl's House Sanatorium for Boys.—M.O. £450.

Evelina Hospital for Children, Southwark, S.E.—H.P. £120.

Freemasons' Hospital and Nursing Home, 237, Fulham-road, S.W.—Res. M.O. At rate of £250.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—Hon. Asst. P.

Liverpool, Royal Children's Hospital, Heswall Branch.—Res. M.O. At rate of £120.

Liverpool, Royal Children's Hospital, City Branch, Myrtle-street.—Two Res. H.P.'s and two Res. H.S.'s. Each at rate of £60.

London Female Lock Hospital, 283, Harrow-road, W.—2nd H.S. At rate of £150.

London School of Hygiene and Tropical Medicine.—University Chair of Public Health. £1300.

Manchester, Ancoats Hospital.—Res. M.O. £150.

Manchester, Ministry of Pensions Hospital, Grangethorpe.—Jun. M.O. £300.

Manchester Royal Infirmary.—Asst. M.O. £35.

Margaret-street Hospital for Consumption, 26, Margaret-street, W.—Hon. Urological S.

Margate, Royal Sea Bathing Hospital for Surgical Tuberculosis.—Two H.S.'s. Each at rate of £200.

Metropolitan Hospital, Kingsland-road, E.—Ophth. S.

Midlothian, West Lothian and Peebles Counties.—M.O.H. £900.

Mildmay Mission Hospital, Austin-street, Bethnal Green, E.—Jun. Res. M.O. £100.

Norwich City.—Clinical Tuberculosis Officer, &c. £750.

Nottingham Children's Hospital.—Res. H.S. At rate of £150.

Oxford, Radcliffe Infirmary and County Hospital.—Hon. Asst. Orthopædic Surg.

Oxford, Wingfield Orthopædic Hospital, Headington.—Asst.S. £600.

Peckham House Mental Hospital, 112, Peckham-road, S.E.—Jun. Asst M.O. £250.

Portsmouth City Mental Hospital.—2nd Asst. M.O. £525.

Portsmouth Royal Hospital.—Cas. O. At rate of £100.

Portsmouth, St. Mary's Infirmary Institution and Children's Home.—3rd Asst. Res. M.O. £250.

Preston, Royal Infirmary.—H S. £150.

Royal Army Medical Corps.—Commissions.

Royal Naval Medical Service.—Twenty Commissions.

Royal Society, Burlington House, W.—Second Foulerton Research Professor. £1400.

Royal Waterloo Hospital for Children and Women. Waterloo-road, S.E.—Non-res. Cas. O. £150.

St. Albans, Hill End Mental Hospital.—2nd Asst. M.O. £450.

St. John's Hospital, Lewisham, S.E.—Cas. O. At rate of £100.

Salford, City of.—Venereal Disease M.O. £750.

Sheffield Royal Hospital.—Res. Anæsthetist. At rate of £80.

Stepney Parish.—Pathologist and Bacteriologist. £450.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—H.S. £150.

Taunton and Somerset Hospital.—Sen. and Jun. House M.O.'s. At rate of £150 and £100 respectively.

Wakefield City Public Health Dept.—Asst. M.O. £600.

Wellcome Bureau of Scientific Research, 26, Endsleigh-gardens, W.C.—Asst. Bacteriologist.

West End Hospital for Nervous Diseases, Gloucester Gate, Regent's Park, N.W.—Sen. H.P. At rate of £150.

Willesden Urban District Council.—Asst. M.O. £600.

The Secretary of State for the Home Department announces a vacancy for an additional Medical Referee under the Workmen's Compensation Act, for the districts of the Bath, Calne, Chippenham, Devizes, Frome, Hungerford, Malmesbury, Marlborough, Melksham, Newbury, Swindon, Trowbridge and Warminster County Courts. Applications should reach the Private Secretary, Home Office, not later than Jan. 31st.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Kilwinning (Ayrshire) and Kirkby Lonsdale (Westmorland).

Births, Marriages, and Deaths.

BIRTHS.

BUTLER.—On Jan. 3rd, the wife of Dr. M. F. Butler, High-street, Penge, of a daughter.

GILBERTSON.—On Dec. 31st, 1927, at Bancroft, Hitchin, Herts, the wife of Dr. H. Marshall Gilbertson, of a daughter.

LANE.—On Jan. 1st, at Malta, the wife of Major J. W. Lane, R.A.M.C., of a son.

ROBINSON.—On Dec. 24th, 1927, at a nursing home, Salisbury, the wife of Major T. T. H. Robinson, D.S.O., R.A.M.C., of a son.

WEBSTER.—At 1, Carden-terrace, Aberdeen, on New Year's Day, 1928, to Grace, wife of A. U. Webster, M.C., M.A., M.B., Fraserburgh—a son.

DEATHS.

HODGKINSON.—On Jan. 6th, at Bradshaigh, Farnham, Surrey, Dr. Alexander Hodgkinson, formerly of Wilmslow, Cheshire.

MAHER.—On Jan. 7th, after an operation, Major-General Sir James Mayer, K.C.M.G., C.B., late R.A.M.C., of "Moorings," Boundary-road, Worthing.

STURGES.—On Nov. 12th, at Ballarat, Australia, Frank Sturges, L.R.C.P., formerly of Beckenham, aged 66.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

RECIPES FOR LIVER DIET.

THE thought of consuming large quantities of liver, as prescribed in the Minot-Murphy diet for anæmia, does not by any means commend itself to the average patient. There are, however, various ways in which it may be served without seeming monotonous or unappetising. The *Journal of the American Medical Association* on Oct. 15th published a series of recipes for cooking liver taken from French and English sources, of which we quote the following as offering perhaps the most tasty dish :—

Ingredients.—1 lb. of calf's liver ; 3 tablespoonsful of grated bread crumbs ; 4 large mushrooms, chopped ; 2 sprigs of parsley finely chopped ; 1 medium-sized onion finely chopped ; ½ teaspoonful of salt and a pinch of pepper. *Method.*—Cut the liver into slices ½ inch thick, and sprinkle each slice with the mixture of bread crumbs, mushrooms, and seasonings ; put in a casserole, pour over it ½ pint of cold water or good soup stock, and bake in a slow oven for three-quarters of an hour.

Further suggestions may be found in a booklet by Florence Irwin. (Belfast : Printed by the Northern Whig, Ltd., Bridge-street. Pp. 12. Price 1*s.*, or 1*s.* 1½*d.* post free.) In the Minot-Murphy dietary she says mammalian liver is recommended, but chicken's liver and lamb's kidney may be substituted for a change ; rabbit's liver should prove milder in flavour than that of pig, sheep, or ox, but pig's liver is also mild. The liver, which must be very fresh, should neither be soaked in lukewarm water and salt nor parboiled before cooking as some authorities recommend, but should merely be wiped with a damp cloth. Simplicity in preparation is generally desirable, the less the liver being cooked the better ; for this reason grilled liver and raw liver sandwiches are recommended, and in the worst stages of the disease raw liver juice is prescribed. Recipes for serving the food in all these different ways and for preparing liver tea are given in the booklet. Soups may be made in a variety of ways, the variation being obtained chiefly by changing the vegetables and ingredients with which the liver is cooked. Some rather more elaborate dishes have been included among the recipes for the sake of variety, the section devoted to casserole cookery containing some of the most palatable. This method of cooking liver should prove useful as none of the " goodness " is lost, and the patient should consume all the sauce and gravy in this and other preparations as they contain much of the liver juice. The following are two of the recipes given in the booklet, the first for raw liver sandwiches, the second for curried liver :—

1. *Ingredients.*—Brown bread and butter ; lettuce, or tomato, or mustard and cress ; mustard, pepper, salt ; 6 oz. liver purée (½ lb. liver). *Method.*—Pass the liver twice through the mincer and rub through a wire sieve. Weigh after sieving. Season it lightly with made mustard, pepper, and salt. Cut some thin brown bread and butter, spread it thickly with the liver, sprinkle some tomato, lettuce, or cress with a drop or two of vinegar, cover the liver with this, and place a piece of bread and butter on top to form the sandwich. Press, and cut neatly. Serve as directed by the doctor. *Note.*—The bread may first be spread with anchovy paste or " gentleman's relish."

2. *Ingredients.*—8 oz. liver ; 1 teaspoonful curry powder ; 1 teaspoonful flour ; 1 teaspoonful good chutney, 2 teacupsful stock ; slice of apple, or ½ stick of rhubarb ; ½ teaspoonful lemon juice ; salt. *Method.*—Start by making the sauce. No fat being allowed in this diet, the method differs somewhat from ordinary cookery books directions for curry sauce. Peel, scald, and chop the onion. Chop the apple or rhubarb. Blend the flour and curry powder in a little of the stock. Put the rest of the stock on to boil, add the onion, apple, rhubarb, and chutney, and cook till the onion is tender. Stir the flour, &c., and simmer 2 minutes longer. Meanwhile cut the liver in small pieces as for any other curry. Add to the curry sauce, and simmer for 15 minutes or till the liver is tender. Add the lemon juice and serve with a little plain boiled rice.

The booklet also contains a copy of Minot's diet for Addisonian anæmia, instructions for taking dilute hydrochloric acid (A. F. Hurst), and other information which many practitioners will find useful.

EARLY MEDICINE IN MARYLAND.

WE have received from the President of the Medical and Chirurgical Faculty of Maryland an address delivered by Dr. Thomas S. Cullen at the Faculty Buildings in Baltimore. It is an interesting record of the development of medical science from the time when a charter for the Province was granted in 1632 to Cæcilius Calvert, second Lord Baltimore by Charles the First. Dr. Cullen quotes largely from the Medical Annals of Baltimore, written by Dr. John R. Quinan and dealing with the medical history of the State from 1608 to 1880, the earlier date being that when a certain John Smith set out from Jamestown in an open barge of 3 tons burden, manned by a crew of 13, hoping to find a westward passage into the Pacific Ocean. This work was brought up to date some 25 years ago by Dr. Eugene Cordell, who took note of the medical happenings in Maryland up to 1899, and Dr. Cullen points out that the time has now arrived for adding a further supplement to the volume. To this end he appeals for an organised effort to gather material, and urges members of the Faculty of Maryland to file away everything of special interest, especially obituary notices and pictures, which they may come across, and to send such records to the library of the Faculty as they accumulate. It would be of great historic interest if similar measures were taken in other of the older American States. There are many records of the earlier times, but apparently no steady effort is made to bring them up to date.

BIRTH CONTROL CLINICS.

REFERRING to the annotation on birth control centres in THE LANCET of Dec. 31st, 1927 (p. 1400), Dr. Norman Haire calls our attention to the Cromer Welfare and Sunlight Centre which has recently been established at 59, Cromer-street, Gray's Inn-road, London, W.C. This is a voluntary welfare centre, with departments for antenatal and postnatal advice, and in addition there is a sunlight department in which expectant and nursing mothers and their children are treated with artificial sunlight. At this Centre any women whose health renders it desirable that they should temporarily or permanently avoid pregnancy are given birth control advice by one of the medical officers. Since extreme poverty may lead to, or aggravate, ill-health, unfavourable economic circumstances are sometimes regarded as sufficient grounds for giving the advice, but it is not a policy of this Centre to advise women not to have children except where there is some definite indication that abstention from parenthood is, at any rate for a time, advisable.

The Centre has not applied for, and does not receive, financial help from public authorities, and is at present supported by a philanthropic gentleman ; all the medical officers give their services without payment. The Centre is only intended for poor people, and will not receive as patients those who can afford to pay a private practitioner. Visits from medical practitioners who are interested are welcomed. The telephone number of the secretary is Museum 7889.

" PRESCRIPTION PAD."

IN response to a letter from Dr. E. L. Hopewell-Ash, which appeared in our columns on Dec. 10th last, Messrs. Schering, Ltd., of 3, Lloyd's-avenue, London, have sent us a specimen of a prescription pad for employment with their Medinal cachets, which are made up to contain either grs. 5 or 10 of the drug. The cachets are contained in small boxes on which the strength is marked outside, the forms of which the prescription pad are composed suggest the larger or smaller dose according to the practitioner's discretion. It is indicated on the form that 12 cachets only have been ordered and that the prescription is *not to be repeated.* The general action of barbitone derivatives is well known, and the object of the proprietors of Medinal is to preclude the possibility of a patient being able to obtain the medicament in any other way than through the medical practitioner.

THE SICK RABBIT AND THE HUNTER.

THE Treasury Department of the United States has issued a timely warning [1] against too close contact with the sick rabbit in the parts of the United States where tularæmia is prevalent. The great reservoir of this tiresome and extremely infectious disease is the wild rabbit, whether of the jack, cotton-tail, or snowshoe variety, and the infection is generally conveyed to man in the spring time indirectly through the tick and in the summer time through the fly. Just now it is the dressing of the dead wild rabbit from which infection is to be feared. Rabbit meat, thoroughly cooked, is harmless for food, and if rubber gloves are worn by those who dress wild rabbits, the personal risk is much diminished, although the employment of immune persons as rabbit dressers is advised where possible, for even the scrupulous technique of trained bacteriologists can hardly prevent dissemination and the Lister Institute some time ago gave up the attempt to maintain the *Bacterium tularense* in the collection of type cultures. Finally, says the U.S. Treasury Department, beware of the wild rabbit which the dog or cat has caught or which a boy has killed with a club, for it is probably a sick rabbit. The hunter should not shoot his rabbits at the point of his gun ; let him be a sportsman and shoot them on the run at 75 yards, when the rabbits bagged will not be sick with tularæmia. Risk, it appears, is only incurred by the type of sportsman who returned triumphant from the desert with the carcass of an old lion which he had found strolling wearily about with a green shade over its eyes.

[1] Public Health Reports, Dec. 2nd, 1927.

A YEAR'S WORK AT LIVINGSTONE COLLEGE.

Livingstone College, Leyton, incorporated in 1900, was founded to teach would-be foreign missionaries how to care for their own health and the health of their colleagues, and how to deal with the everyday diseases of the people of the country in which they are to work, when living far removed from qualified medical aid. The College admits men and women of all nationalities and religious denominations, both missionaries going out for the first time and those on furlough. The full course of training covers one academic year and the College now numbers on its roll of past students nearly 1000 missionaries working in all parts of the world. The past year has seen the largest entry since the College was started. During the year 100 students from seven countries, and representing 28 missionary societies, have received practical and theoretical training on the care of health and in the treatment of tropical diseases, which an intelligent trained layman can be expected to carry out. The annual report for 1926–27 shows a record of good work, and emphasises the fact that a little knowledge is by no means necessarily a dangerous thing; if rightly used "a little knowledge grows by using it."

THE WICKER BUGTRAP.

SOME interesting remarks in THE LANCET of July 16th last year on the prevalence of bed bugs in this country a hundred years ago suggest how much we owe to sanitary legislation and the inculcation of cleanliness. Reference was made in the note to the "Bug Catcher to his Majesty," who before 1837 held a Royal Warrant for this purpose, and *Cimex lectularius* held sway at any rate as late as 50 years ago, at which date there existed a well-known hotel in London which by commercial travellers, who used it, was generally referred to as "buggy." So prevalent were these parasites, at any rate in the earlier years of the nineteenth century, that basket traps were made to catch them, advantage being taken of their habit of retiring for rest and digestion after their bloodthirsty debauch. These baskets were made of wicker and placed behind the bolster across the bed, as we are reminded in a note in the current issue of *Man* which is published under the direction of the Royal Anthropological Institute of Great Britain and Ireland. Illustrations are here given of a bug trap, similar to those used in the early 'sixties as part of the domestic furniture of middle-class households, which has been placed among the archæological exhibits in the museum at Cambridge. Although superior households tried to protect themselves against the pests, whom a judge has classified as "dangerous insects capable of causing assessable injury," among the common people they were regarded biologically as related to symbiosis rather than to parasitism—they argued the existence of a beneficent Creator who for poor folk provided a substitute for the periodical bleeding deemed necessary to health by their richer neighbours.

INFECTIOUS DISEASES AND ASEPTIC NURSING TECHNIQUE.

OUR knowledge of the means by which infectious diseases are spread is still indefinite, yet, by keeping within certain limits and observing certain rules, their incidence can be reduced. If this object is to be attained the primary need is that the physician in charge of the infectious case must know all the possible leakages of infection and how to stop them. But he only sees his patient for a few minutes each day, whereas the nurse is never absent and is, moreover, in contact with the other inmates of the hospital or private house. In all small matters she is responsible for the technique which prevents transmission to others, and although she receives her instructions from the doctor, she cannot do her part well unless she herself thoroughly understands the principles on which she is relying. Dr. Richardson, in the preface of his recent book, "Infectious Diseases and Aseptic Nursing Technique,"[1] points out that the ordinary text-book written for the physician is too elaborate for nurses, and he has tried to write a simpler book. In the first part, after a brief discussion of the principles of infection and immunity, he describes all the diseases which are infectious. The particular signs, symptoms, complications, and treatment of each are given and the means by which they are transmitted. This is followed by a very useful chapter on the nursing of infectious diseases at home, in which isolation, the treatment of contaminated dishes and clothing, the disposal of excreta and refuse, and discharge from isolation are discussed. The second part of the book deals with technique in hospital.

Dr. Richardson explains that here it is specially difficult to prevent the spread of infection, because the causative organisms are most virulent while secretions and excretions are in a fresh state. Organisms usually enter the body through the mouth or nose, the infection being most often conveyed by contaminated hands or by direct contact. A hospital may be usefully divided into "units." A "unit" is an infected area which includes the patients in any room or ward who have the same disease. It includes the furniture in the room, clothes, and all instruments and applications used by patients in the unit. Indirect contact between units is prevented by employing a technique similar to that used by surgeons when operating. This Dr. Richardson describes as medical asepsis. He then explains how this may be attained in a hospital and the application of its principles in hospital administration. Finally he describes the best methods of disinfection. The book is simply and clearly written and will be appreciated not only by nurses, but by students doing "fevers" and by practitioners.

[1] By D. L. Richardson, M.D., Superintendent of Providence City Hospital, Providence, R.I. London: W. B. Saunders Company. Pp. 182. 7s. 6d.

POISONING BY TETRACHLORETHANE.

TETRACHLORETHANE is known to be a powerful narcotic acting on the central nervous system and its inhalation in the form of aeroplane dope gave rise to some of the cases of toxic jaundice among munition workers during the war; but instances of direct poisoning are rare, and interest attaches to a case reported by Major R. A. Hepple, R.A.M.C., in the *Journal* of the Corps for December, 1927. The patient, aged 21, was unconscious all the 20 hours he survived; coma was almost the only symptom. His stomach was washed out, but the heavy tetrachlorethane was not all evacuated. Respiration gradually failed, and the temperature, which at first measured 96·2° F., became 104·2° F. just before death. At the post-mortem examination small erosions were seen in the œsophagus, stomach, and small intestines; cloudy swelling and congestion of the liver and kidneys, congestion of both pulmonary bases. The thymus weighed ½ oz. The stomach contained about 6 oz. of fluid, from which 12 c.cm. of tetrachlorethane was recovered by distillation. A single cubic centimetre given to a healthy rabbit rendered it comatose in ten minutes.

NEW PREPARATIONS.

FROM the Clayton Aniline Company, 40, Southwark-street, London, S.E., we have received a specimen of *Prokliman*, manufactured by the Society of Chemical Industry in Basle. It is an ovarian hormone compound designed to combat climacteric manifestations. It has received high praise in well-known German general and special medical journals, and Dr. Walter Braun, among others, writing in the *Zentralblatt für Gynakologie*, details the good results obtained by treating both women whose ovaries had been removed before the menopause and women whose climacteric had occurred in the usual way. The preparation has been added to the list of "Ciba" brand pharmaceutical specialities.

Concentrated Fluid Extract of Liver. For this preparation, which emanates from the Armour Laboratories in Chicago, and is distributed from Queen's House, Kingsway, W.C., it is stated that in each ounce of the extract 8 ounces of fresh and specially selected material is represented. The product is prepared from fresh calf liver, the manufacture of the alcoholic extract taking place whilst the liver still retains natural heat. Recent research has shown the value of liver preparations in certain deficiency disorders, and we may refer here to the paper which appeared in our columns[1] last November by Dr. John Anderson and Dr. E. I. Spriggs on the Minot-Murphy liver diet in Addisonian anæmia. The value of liver diet in sprue is illustrated in the same issue by Dr. Carmichael Low and Mr. W. E. Cooke.

We have received from Messrs. Coates and Cooper, 41, Great Tower-street, London, E.C., two preparations from the laboratory of Messrs. Reed and Carnrick, of Jersey City, N.J., for whom they act as distributing agents: (1) *Protonuclein*, (2) *Pancrobilin Pills*. The preparations are designed to meet glandular insufficiency as revealed by recent work on the inter-relations of the natural secretions. The claims by the manufacturers, which accompany the samples, are very large and obviously require endorsement from the records and notebooks of practitioners whose verdicts result from actual experience in practice.

Messrs. Roberts and Co., of 76, New Bond-street, London, W., have sent us *Elixir Sedoval* which is a bromide salt of strontium combined with an extract of valerian; the objectionable odour of the latter has been eliminated so that the association of the two products is free from disagreeable odour or taste. A tablespoonful of Sedoval contains grs. 6 of strontium bromide and 12 minims of extract of valerian. The sedative action represented by its make-up is obtained in nervous manifestations, in various forms of hysteria and in insomnia, if such a dose be taken two or three times a day, varied in accordance with the directions of the physician.

Clinical Address
ON
PERNICIOUS ANÆMIA.*

By LORD DAWSON OF PENN.

THE conception of pernicious anæmia is interesting from the way it has grown and from the problems it provokes. Interest consists in not only having a past but a future.

Let me recall the landmarks in our knowledge.

Although the first case was reported by Combe,[1] of Edinburgh, in 1822 and in 1851 Barclay [2] noted the glossitis which is an occasional feature, it was Addison [3] in 1855 who gave us the first conception of this disease; and it is worth recording that during its study he "stumbled upon the curious facts" (to use his own words) which led to his discovery of Morbus Addisonii. He described the clinical picture; the insidious onset; the occurrence in both sexes beyond middle life, the body as "blanched, smooth and waxy" and "flabby rather than wasted"; the breathlessness and palpitations; the progressive langour and prostration, and the continuance, in spite of all remedial efforts, to a fatal termination. He recognised the disease as something apart and without discoverable cause, and termed it "idiopathic" to make a distinction from cases presenting "the usual causes and concomitants of the anæmic state." The remarkable remissions seem to have passed unnoticed, but when one reflects how far off are those days and how primitive were the then methods of blood examination, one thinks with admiration of the clinical acumen which Addison's description discloses. And when it is further recalled that 17 years later Biermer [4] described the disease yet failed to distinguish it from certain other grave anæmias, it seems only just that one of its titles should be "Addison's anæmia."

OBSERVATIONS AND THEORIES.

The next link was forged in 1876 by Cohnheim,[5] who described megaloblastic degeneration of the bone-marrow as the cause of the disease; that is, he held that the bone-marrow failed in its function of the production of blood—hence the anæmia.

Of the associated conditions atrophy of the gastric mucous membrane was noted by Fenwick [6] in 1877, degeneration of the posterior columns by Leichtenstern [7] in 1884, and achlorhydria by von Noorden [8] in 1891. Next came Ehrlich,[9] who held that the megaloblastic changes in the marrow were regenerative and compensatory to blood destruction, thus raising with Cohnheim the issue, which yet remains unsettled, whether the changes in the marrow are degenerative or regenerative—under-production or compensatory over-production.

In 1900 the work of Hunter [10] brought out the important part played by septic teeth. Secondly, he made gravimetric estimations of the hæmosiderin in the liver, showing that in amount it far exceeded that found in any secondary anæmia, and postulated hæmolysis in the portal veins. Further, he emphasised that the disease is not merely an affection of the blood, but is characterised by features such as glossitis, achlorhydria, diarrhœa, and degeneration of the spinal cord, some of which may precede the anæmia.

Hunter espoused the view of Ehrlich as opposed to that of Cohnheim—namely, that the changes observed in the marrow are regenerative and intended to compensate for hæmolysis produced by bacterial toxins. That hæmolysis on a considerable scale does take place in pernicious anæmia is suggested by the intense prussian-blue reactions in spleen, liver, kidneys, lymphatic glands, and synovial membranes. Further support for this view is found in the excess of bilirubin in the plasma, and of urobilin in the urine and fæces. I stress this evidence because recent original work (Zadek,[11] Peabody [12]) has led its authors towards the conclusion that the anæmia owes its existence to defective blood-formation in the marrow, thus reverting to the view that Cohnheim put forward in 1876. The two opinions might be reconciled—and they are both based on careful observations—by assuming that the blood turned out by the marrow is so abnormal as to be an easy prey to destruction.

After Hunter's work in 1900 we come to the demonstration of reticulocytes, by Cesaris-Demel [13] and Chauffard [14] in 1907, by vital staining. If a blood film is treated with brilliant cresyl blue before the use of a fixative a network can be shown in the cytoplasm of the red cells. This network has been demonstrated by Sabin [15] in the earliest red cells of the chick embryo at a time when they are still nucleated and is to be considered a cytoplasmic substance. It disintegrates and disappears as the cell becomes mature. The reticulocytes, therefore, afford a criterion of youth, and their number in a blood preparation is an index of the activity of normal blood regeneration. Thus whereas, in films of normal blood, reticulocytes may be present to the extent of, say, 1·5 per cent., in active blood formation they may reach 15 to 30 per cent.

ORIGIN AND ABNORMALITIES OF RED CORPUSCLES.

Here I must step aside for the purpose of clarity and consider certain happenings in the rise and fall of the red blood cell. My digression must be brief and controlled or we shall become submerged in the morass of the higher hæmatology.

In the embryo there appear blood islets, some in the yolk-sac and others in the primitive liver. These are aggregations of cells of which those that are centrally placed become primary blood cells (hæmocytoblasts) and those that are peripherally placed become an endothelial envelope which is the first manifestation of the reticulo-endothelial system. These primitive blood cells take on the function of carrying hæmoglobin and become primitive erythroblasts. The latter in turn become large cells, some of which remain nucleated and are called megaloblasts, whilst others lose their nuclei and become megalocytes. These forms belong only to the blood of the fœtus and are not found in post-natal life either in blood or marrow, except in pathological states like that of pernicious anæmia. In postnatal life the primitive erythroblasts are derived from the reticulo-endothelium, proliferating from the endothelial cells of the capillaries of the marrow. From these arise the normoblasts which lose their nuclei and ultimately become the normal red cell.

Punctate basophilia is an abnormal change in a young red cell and therefore does not appear in the normal development of blood (Ferrata [16]). Polychromatophilia is likewise evidence of immaturity of the red cell and is a normal stage in the regeneration of blood. Anisocytosis is to be regarded as evidence of hurried regeneration, and is not a strictly normal phenomenon. Poikilocytosis is never seen in health and should be looked on as a more definitely abnormal mode of regeneration than is anisocytosis. Lastly we come to megalocytosis, which is an important characteristic of pernicious anæmia and may be regarded as *the* most important diagnostic feature in the blood picture. It can be demonstrated by two methods, the first being the extreme variation from normal as shown by Price Jones [17] in his skilled and laborious technique for measuring the diameter of the red cells, and the second being the increased average volume of the red blood cell as Alder [18] showed by a viscosimetric method. Megalocytosis accounts for a colour-index above unity, for since the normal red cell is already saturated with hæmoglobin, only a larger cell can contain more. The exact mode of production of the megalocyte is disputed; it is most probably a direct derivative of the megaloblast.

The megaloblast, though found widely distributed throughout the hæmatopoietic tissues of the fœtus, is

* Based on communications made to the Brighton and Sussex Medico-Chirurgical Society and the Windsor and District Medical Society.

absent in those of the normal adult. However, in certain severe anæmias a reversion to this fœtal type occurs, and one of the most characteristic findings in pernicious anæmia is a megaloblastic activity of bone-marrow, spleen, and liver, with the occasional escape of megaloblasts into the blood. The bone-marrow in pernicious anæmia has been studied in life by trephining the tibia, and Zadek and Peabody have shown that during relapses there is an active proliferation of megaloblasts, which so increase and multiply as to occupy much of the available bone space, the fat cells collapsing and their contained fat disappearing. At the same time a few normoblasts and red cells are found, from which we may infer that the megaloblastic proliferation seems to serve an unknown and feeble physiological purpose; perhaps an abnormal need calls forth an abnormal effort. On the other hand, with a remission the megaloblasts in the marrow more or less disappear and a preparation shows normoblasts and mature red cells less closely packed and with marrow fat easily discernible. With this change in the marrow picture, and as a sequel to it, the red blood count correspondingly improves.

Taking advantage of the fact that the proportion of reticulocytes is the best criterion of active blood formation, Peabody searched for these immature forms in the blood of pernicious anæmia during a relapse and found that their percentage was not higher than that found in normal blood, which accords with the view that the relapse is the result of diminished blood formation. On the other hand, in anæmias which are admittedly hæmolytic, like that of acholuric jaundice, the reticulocytes reach 20 to 25 per cent., showing that a compensatory blood formation is in active process. These considerations have led our Swiss and American colleagues to conclude that the immediate cause of pernicious anæmia is a defective formation of blood in the marrow, due to the reversion of the cellular content of the marrow to the fœtal megaloblastic type.

Possible Bacterial Cause of Hæmolysis.

Diminished blood formation, however, cannot be the whole story. That there is definite hæmolysis in pernicious anæmia cannot be doubted when one recalls the excess of free iron demonstrable in the liver, spleen, kidney, and even synovial membranes, or the excess of plasma-bilirubin, as demonstrated by the van den Bergh [19] test, and the excess of urobilin in the urine and fæces.

There are grounds for associating bacterial toxins with the cause of this hæmolysis. From time to time a case occurs in which a close connexion with a septic focus can be established; septic teeth can be quoted as an example. The following case suggests the operation of a toxin producing Addison's anæmia.

Some years after an uneventful appendicectomy a young woman had acute intestinal obstruction. At the operation inches of gangrenous ileum were removed. Within two days symptoms of obstruction recurred, and a second operation was performed, involving a second anastomosis. Life was preserved, but ever afterwards intestinal function was impaired; there was distension and liability to constipation and diarrhœa, but she lived her life, though with limitations, and even married. Later she developed signs and symptoms resembling those of pernicious anæmia, and these persisted with remissions to her death. *B. welchii* was recovered in predominance more than once from the intestinal content.

Moench, Kahn, and Torrey [20] in an examination of the stools in 35 cases of pernicious anæmia showed that *Bacillus welchii* gives uniformly higher counts than normal. However, none of the strains they isolated could be shown to be more hæmolytic or pathogenic than *B. welchii* from the stools of normal persons. They consider that this organism comes into play because of its increased numbers and activity at an abnormally high level in the alimentary tract, where absorption is more active. That the cause of the upward spread of colonic organisms is achlorhydria is a view now widely held. Cornell [21] showed that *B. welchii* injected subcutaneously into rabbits caused an anæmia with constant anisocytosis. Kahn and Torrey,[22] working at the same time on the effect of intravenous injection of the toxin in monkeys, obtained very similar blood pictures with high colour indices and leucopenia. According to Gulland [23] these workers have since gone further. Having damaged the gastric mucosa of monkeys and fed them with cultures of *B. welchii* they have produced in the blood and tissues changes identical with those found in pernicious anæmia in the human being.

Constitutional Factors.

There is evidence of other factors at work, especially constitutional factors. Thus achlorhydria, so constant and so often for years a precursor of the disease, has been shown by Hurst [24] to exist in the blood relatives of patients with pernicious anæmia.

In this disease much depends on a patient's reaction. That is why it occurs in some with so little apparent provocation and in others it keeps away in spite of every provocation. The make-up of the individual is important and is illustrated by the proneness of pernicious anæmia to occur in certain families—a proneness which finds an interesting analogy in the incidence of the form of anæmia due to *Dibothriocephalus latus*. In certain regions of Finland, although this tapeworm is common in the human intestine, the anæmia is nevertheless rare. Thus in only a small percentage of the infected did Schauman [25] find the anæmia and amongst these the incidence was largely familial. Further, it is now known that this susceptibility is also racial, for in areas where Finns have brought the parasite to North America, though Americans and Finns alike become infected only Finns (and then only certain families) develop the anæmia, whereas the Americans escape. This bears directly on our conception of the ætiology of pernicious anæmia, for dibothriocephalus anæmia shows a blood picture identical with that of idiopathic pernicious anæmia and is caused by a hæmolytic toxin which can be isolated from the segments of the parasite.

Liver Treatment.

Let us now pass to the treatment of pernicious anæmia by feeding with liver and liver extract. This is based on the results of experiments on dogs by Whipple and Robscheit-Robbins.[26] These demonstrate that fresh liver contains some principle which promotes blood regeneration. It was first applied to cases of pernicious anæmia by Minot, Murphy, and Cohn,[27 28 29] who found that on a diet rich in mammalian liver (about 200 g. cooked weight daily) there was rapid and striking improvement, with prompt increase of the red blood corpuscles in almost every case. About the fifth day the reticulocyte count rose often to 14 per cent., the rise corresponding to a fall in the plasma bilirubin as the result of diminished blood destruction. This was followed by a prompt and steady increase of the red cell count. Thus in 90 cases the average numbers of red cells rose from 1½ to nearly 4½ millions in two months. Other forms of anæmia show striking benefit under the same treatment.

Active extracts of liver are now being used with success. Thus Spence [30] employed a liver extract made by the method of Cohn. He used 20 to 25 g. a day and his cases showed definite improvement after seven days. Another method which avoids the use of raw or cooked liver consists in drying liver in vacuo and powdering it at a low temperature. This powder is easy to take, and two ounces of it correspond to eight ounces of fresh liver substance. We may hope that in the near future the composition of the extract may be determined so that it can be synthetically prepared.

In conclusion, three possible links can be traced in the chain of ætiology: achlorhydria, abnormal flora in the upper half of the alimentary tract, and the absence or insufficiency of a specific function of the liver. What is the interrelation of these factors and the rôle played by each in the causation of the disease remain a matter for the future to decide.

An Address
ON THE
EDUCATION OF MEDICAL OFFICERS FOR SERVICE IN THE TROPICS.

Delivered at the International Continuation Course of the League of Nations, Nov. 24th, 1927,

By ANDREW BALFOUR, C.B., C.M.G., M.D. Edin., F.R.C.P. Lond. & Edin.,
DIRECTOR, LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

Part II.*—TROPICAL HYGIENE.

A story is told of a distinguished sanitarian in the Indian Medical Service. He was given a dinner on the occasion of his retirement, and heartily congratulated on the result of his labours in the cause of tropical hygiene. Replying to the toast of his health, he said that he attributed whatever success had attended his efforts to two factors: first, that he possessed an acute sense of humour; and, second, that he possessed no sense of smell!

If these were indeed requisites for the success of a tropical sanitarian the outlook would, I fear, be gloomy for teachers of tropical hygiene, as one cannot instil a sense of humour where it is lacking, and the production of anosmia would entail rather a serious operation. The colonel was joking, and yet there is no doubt that unless a tropical hygienist has a sense of humour he is likely before very long to become a corpse or a neurasthenic, while it is equally true that at times he wishes his olfactory sense was absent or blunted, though, with all due deference to the jovial colonel, the possession of a good "sanitary nose" is a great asset in public health work. I know of at least one unfortunate who perished from food poisoning owing to the fact that he had lost all sense of smell. However humorous or the reverse the student may be, whatever his powers of smell, one thing is certain, he must have been well grounded in those principles of tropical medicine we have already discussed before he undertakes the study of tropical hygiene. Some people will tell you there is no such thing as tropical hygiene. In one sense this is true enough. The principles governing hygiene in the tropics are those which apply to the hygiene of countries with temperate climates. On the other hand, the application of these principles is often very different in the tropics from their application, say, in Europe. It is in practice, not in principle, that the hygiene of countries in the torrid zone differs from that of those which are termed Occidental.

The practice differs for various reasons. In many cases the conditions are primitive and must be met by what is called field hygiene, partly on account of the environment, partly because there is a paucity of funds. Too often bricks have to be made without straw, and the man blessed with ingenuity finds every scope for it. Again, the populations which have to be served and handled, even if not primitive, are usually devoid both of a sanitary sense and a sanitary conscience, and measures tried and proved amongst educated communities fail lamentably when introduced amongst races which are backward from the hygienic standpoint. Yet, again, there are customs and prejudices, religious and otherwise, which have to be overcome and which may prove insuperable barriers.

Equally important is the fact that the ætiology of the communicable diseases encountered differs in many instances from that of the maladies met with in non-tropical lands, that the rôle of the arthropod is, if not paramount, at least greatly in evidence, and that the climatic conditions usually tend to aggravate all forms of nuisance and of danger to health. These are commonplaces, but they are worth bearing in mind, for any training in tropical hygiene must take cognisance of them, and though, as ever, experience is the best teacher, yet the student can be given some idea of what he has to face and how best he should face it.

Subjects the Student should Study.

In the first place, he must be taught how to look after himself in the tropics, for a blind leader of the blind will not only forfeit respect, but may lead some of his flock astray, and perhaps bring his own career to a sudden and disastrous termination.

Climatology and Acclimatisation.

A course in tropical hygiene should, then, commence with a discourse on climatology, and should briefly and succinctly indicate the physiological and pathological effects of tropical conditions on the life and health both of the indigenous native population and of the white sojourners and settlers. Here, as elsewhere throughout the course, if there be time, it is well to direct attention to what was known on this subject in the olden days when there was no bacteriology or protozoology, and no real medical entomology. A few quotations from a book like Johnson's "Influence of Tropical Climates on European Constitutions" are likely to interest the student and impress upon him the fact that, despite all our new knowledge, the climate of the tropics still remains, as of yore, a menace in the background and cannot be lightly discarded. It is, I think, better to employ the historical perspective in this way throughout, giving point to the subject under discussion, rather than to embark on a disquisition upon the history of tropical hygiene which would take up far too much time, probably weary the majority of the audience, and irritate those of them with severely practical minds who want to get down to what in vulgar English is called "brass tacks," that is to say essentials, essentials both for examination purposes and for their work abroad. In advancing a plea for the intro-

duction of occasional historical references I realise I am advocating rather an ideal type of course for the necessity of imparting a vast deal of important information within a very limited period (a point to which further attention will be paid) may well exclude any such excursions. Yet in the study of hygiene, more perhaps than in the case of any other subject, it is advantageous to let the lessons of history speak for themselves. They are impressive and should engender both faith and hope, showing the student that, even if some of the details he has to master are dry, the collective effects of the knowledge gained and applied by his predecessors has been remarkable and stimulating him to fresh efforts in a good and promising cause.

Not only must the effect of climate on native races be considered but, as must be evident from what has already been said, some attention must be directed to the native races themselves, to their habits, customs, religious prejudices, superstitions, and so forth. It is, of course, impossible to go minutely into such matters. A few striking illustrations should be selected, one, let us say, from pagan negroes, another from Mohammedan Arabs, a third from Hindus and Hinduism, a fourth from the "heathen Chinee." This will suffice for lecture purposes, and the student can supplement what is told him from the literature, as, for example, from "Mother India," that astonishing but well documented record from an American source, or, in due course, from personal experience amongst the people with whom he is brought into contact. Some men can, of course, envisage their future surroundings and possess imagination which helps them to foresee and to cope with difficulties, but others never seem to realise what the future has in store for them, and without some guidance will, on reaching the tropics, feel like fish out of water for quite a lengthy time, during which they may either do very little good or a great deal of harm.

Something, I think, should also be said about handling native races. It is, of course, not easy to formulate a set of rules generally applicable, but there are certain cardinal principles which can and should be enunciated, and will be found of value to the tyro.

The subject of the white man in the tropics is an easier one, though it is a difficult task to deal adequately and to advantage with the vexed question of racial acclimatisation. It must, however, be attempted and a synopsis given of the various views at present held, stress, of course, being laid on those findings which admit of no dubiety. Here some reference must be made to sexual hygiene, for it plays an important part in this acclimatisation question, more especially in connexion with the onset of neurasthenia. Health officers should be alive to this aspect of the problem. A clear differentiation should be drawn between the effect of the dry and of the moist tropics on the comfort and health of the white resident, and attention should be directed to the modifying influence of altitude.

Personal Hygiene.

The subject of personal hygiene may next claim attention, and, while much that is said will apply to the students themselves, the discourse must not be limited to the prophylactic measures they should adopt against climatic effects and the usual trials and dangers which beset white men in the tropics, but must include the care and attention which have to be exercised by non-medical women, and in the case of infants and young children. Here let me say that a very safe guide is the interesting and useful little book compiled by Dr. Balfour Kirk and entitled "Hints on Equipment and Health for Intending Residents in the Tropics." The subjects to be considered under this heading are numerous and varied. The necessity for inoculation against diseases of the so-called enteric group must be emphasised and a definite statement made on the policy of not inoculating infants and young children, the reasons for such exclusion being given. There should be some reference to the advisability or otherwise of submitting to inoculation against plague and cholera. The value of vaccination against small-pox must be affirmed with no uncertain voice, for in the tropics variola is a disease with which one cannot afford to trifle. It must not become the sport of politicians, the plaything of cranks, the theme of the ignorant, even the well-meaning ignorant. Clothing, equipment, both medical and sanitary, the regulation of life and habits in a hot country for all ages and both sexes, must be discussed and special stress should be laid on the value of rest. Not only the care of the body, but the care of the living quarters, including methods for mitigating heat and glare, should be dealt with, from the humble hut to the storied house, and on no account must the lecturer omit the important question of native servants. A little knowledge may be a dangerous thing, and while it may be admitted that to know the curious, often disgusting, and not infrequently dangerous habits of the native servant thoroughly would necessitate donning his pigmented skin and viewing the world through his eyes, "forewarned is forearmed," and the potential risks which the native servant represents should be impressed upon the class in a general way, and illustrated by a few striking examples such as the cholera carrier, the ejector of saliva upon laundry material, the user of the filthy kitchen cloth.

Of equal importance is the matter of the housing of native servants and the need of frequent inspection of their quarters, as well as of the kitchen where the cook and his myrmidons, often masters of their trade, may inadvertently add death to the pot.

Maternity and child welfare is a big subject, but it cannot be omitted, even though only a few of the special difficulties imposed by the tropics can be touched upon and reference made to the placental transmission of such maladies as malaria and ankylostomiasis. Its bearings, both on the white and the indigenous race, must be considered, and, so far as maternity in native races is concerned, this part of the course will link up with the first lecture, for native habits and customs very often play a paramount part in the hygiene of pregnancy, childbirth, and the puerperium. Similarly the question of child welfare, both amongst the white and coloured sections of a tropical population, is intimately associated with that of food and dietetics which we are fast approaching.

Housing.

Housing in the tropics may, however, with advantage be first considered if only because it will embrace markets where food is housed or stored. There can be no doubt that housing is one of the most important topics in our ideal course. Anyone who has, as I have, seen a tropical country redeemed from barbarism and the early efforts of a white race to obtain a footing in it, will admit that hygienic measures are comparatively futile until decent houses are provided. For example, the morbidity and mortality amongst British officers in the Bahr-el-Ghazal Province of the Anglo-Egyptian Sudan were lamentably high until more or less settled conditions were forthcoming and they were able to occupy houses giving a measurable degree of comfort and protection.

In the case of native races also housing plays a prominent part. This has been specially recognised in Kenya Colony where, again and again, the director of the medical department and the chief sanitation officer have emphasised the need of revolutionising native housing if disease generally, and notably plague, is to be mastered. The Dutch in the East Indies have not only recognised this need but have gone a long way to meet it. The whole subject can be made very interesting, as well as instructive, if properly handled, and the lecturer should indicate the good points in native housing methods where these exist, as they do exist, and caution would-be reformers against misdirected zeal. In the case of European houses the question of screening against flies and mosquitoes will come up for consideration, and, in my opinion at least, the students should be

warned to discount the statements of old stagers in certain tropical countries to the effect that white men and women cannot live in screened houses owing to their stuffiness and the feeling they engender of being "cribbed, cabined, and confined." It is not a question of stuffiness but of stuff and nonsense in many instances and, even where, in sheltered areas, screening may make a house somewhat close, the advantages far outweigh the disadvantages. Partial screening versus total screening demands consideration, and here not only the screened verandah but the verandah as a verandah may suitably form the subject of discourse. In other words, should tropical houses be furnished with verandahs? One can understand the director of a public works department jibbing at expense and becoming an opponent of verandahs, but it is strange to find medical officers decrying their need and value. Possibly some of the opposition is due to the fact that so many verandahs are wrongly constructed. How rarely are they properly ventilated! An unventilated verandah often permits of a cushion of hot air lying up against the protected side of the house and so in part defeats its own ends. Given adequate ventilation, a verandah is an essential part of a tropical residence, and the prospective health officer should be duly apprised of that fact.

Year by year hygiene in the tropics approximates more closely to that of temperate climates. In fact, in large tropical cities many aspects of public health, especially those related to sanitary engineering, do not greatly differ from those which present themselves in urban areas in Europe and the United States. Hence, when teaching tropical hygiene here, it is of great importance to give students every opportunity of visiting works and plants concerned with the public health from which useful and practical lessons can be drawn.

So far as housing is concerned, should anything be done in this direction? I think not. True, if there were ample time it might be advantageous to have a look at bungalow construction and to familiarise the student with certain aspects of house construction, but these are matters affecting rather the engineer and the sanitary inspector, and, if the future health officer gets a clear grasp of the principles underlying house construction in the tropics, it should be sufficient for his purpose. His function in this connexion will be, as a rule, advisory, not executive.

Under the heading of housing, however, come such buildings as markets, slaughter-houses, hospitals, schools, prisons, and factories. If it can be arranged, visits should be paid to all or some of these, the most modern and up to date being chosen for the purpose. The most important are, I think, markets, slaughter-houses, and prisons, for the health officer in the tropics is constantly concerned with questions having a bearing on buildings constructed or to be constructed for these three purposes.

While, as a rule, markets and slaughter-houses in the tropics are, even when primitive, built on reasonable and sensible lines, this is often far from being the case with prisons. I think I have only once seen in the British tropics a prison built on lines corresponding to those followed in this country and which certainly possess some advantages from the hygienic if not from the economic standpoint.

Hospital and school construction is perhaps best studied from plans of good types already existing in the tropics, and of these there is now no scarcity, though they are not always easy to obtain. The housing of native labour is a matter requiring very careful attention, and students should be told what has been done at the mines on the Rand, in Natal, in the Panama Canal Zone, and elsewhere. A book like Pearson and Mouchet's "Hygiene of Native Compounds" is of great value and leads me to say something on the subject of camps.

Although, as indicated, the health officer destined for the tropics should be given an opportunity of becoming practically familiar with various developments in public health and sanitary engineering in a country blessed with a temperate climate and possessing the doubtful benefits of civilisation, he should at the same time gain instruction, if possible, in *field hygiene*, those comparatively rough-and-ready methods, those shifts and improvisations, as well as those special adaptations which are usually a feature of army sanitation during active service. For this purpose, here in London, we are in the habit of sending our students for a day to the Army School of Hygiene at Aldershot, where the field demonstration and museum afford excellent practical instruction in everything pertaining to camp hygiene and that of an army in the field.

I cannot leave the subject of housing without a brief reference to *town planning*. Something should be said about the latter, if only to enlist the student on the side of those who deplore the mistakes of the past, seek to guard against their repetition, and to remedy them as far as may be. The expert town-planner is a specialist, but every health officer in the tropics should be a sturdy advocate of town planning along sound lines and, in the future, more than in the past, his opinion is likely to be sought in the laying-out and reconditioning of townships.

Food and Dietetics.

Food and dietetics together form one of the most important sections of the course. Many lectures might well be devoted to it, but even a limited survey can be made informative. One has again to deal, in the main, with general principles, but it is, of course, advisable to devote special attention to food deficiency and its relation to such diseases as beri-beri, scurvy, and pellagra. Some of the commoner tropical foodstuffs, more particularly those fruits (bananas) and cereals (maize and millet) which form the staple dietary of some native races, will be considered, as will the use and abuse of condiments. Milk and its products require special attention for, complicated as the milk question is in a country like England, it is still more complicated, at least in certain directions in, let us say, India, while, in the tropics generally, the cow is not the almost universal provider of lacteal fluid that she is in this and many other lands. If, as Cicero said, we are "possessed with thoughts of the kitchen," and our students are, like Horace's youth, devoted to kitchen studies, such thoughts and studies must not be limited to what is prepared and cooked in the kitchen. Far from it, for the hygiene of food in the tropics is a matter to which special attention must be paid. Hence the lecturer must deal with the handling and inspection of food, its preparation, its storage and preservation with a dissertation on cold storage. He must refer to tinned and bottled foods, a subject which will lead him on to food poisoning and its association with kitchen hygiene and man's enemy, the fly. The hygiene of milk, of aerated waters, and of ice possesses no little importance, and students should certainly be taken to see a pasteurising plant and, if possible, should visit both a bad and a good aerated water factory. If only one of these is available I should say "go to the bad," for it will teach more and better lessons than the up-to-date place and, in any case, there are few localities in the tropics where modern and elaborate plants are or can be installed.

Water and Water-supplies.

We now come to the great subject of water and water-supplies, and this perforce must, for the most part, be handled along lines familiar in all courses on hygiene, under such headings as sources of supply, classification of waters, sources of pollution, collection, protection and storage, distribution and purification. In addition, the relative values of bacteriological and of chemical analyses must be discussed and, so far as bacteriology is concerned, the suitability or otherwise for tropical work of the methods and standards adopted for use in temperate climates requires consideration.

Stress should be laid on the special value in the tropics of a careful personal inspection of the source of supply and of its surroundings, a form of examina-

tion at least as important as any laboratory procedure, and in certain circumstances much more important. Another matter which must be impressed upon the student is the absolute necessity for making adequate provision for the removal of waste water before introducing an ample water-supply into any settlement. This possesses an unwonted significance in the tropics, as neglect to secure proper drainage is likely to be followed by retribution in the shape of mosquitoes and malaria. When the problems of purification are being expounded it should be remembered that mechanical filters and chlorination now play a great part in water hygiene in the tropics, and every effort should be made to enable the students to see for themselves rapid filtration and chlorination in actual operation. More primitive methods of purification of water, or of securing a satisfactory supply, under discouraging conditions, both on a small and a large scale, should be indicated and, naturally, wells, both shallow and deep, will claim a fair share of attention. A student who cannot explain how a shallow well can be effectually protected from pollution, and how, if polluted, its contents should be treated, is certainly not a satisfactory class product.

"Conservancy."

Under the general title "conservancy," the collection, removal, and disposal of both excreta and refuse fall to be considered, and it is often convenient to deal here also with sullage water and surface drainage. Mrs. Humphry Ward, the novelist, in the person of one of her characters, once said: "In my youth people talked about Ruskin, now they talk about drains." Drains, however, need not occupy much of the time of our lecturer on tropical hygiene, because in most parts of the tropics they do not exist. True he must say something about them, but he is much more concerned with simple sanitary appliances, and the pail unhappily bulks more largely in hot countries than the drain or sewer. I remember Dr. Cameron Blair, of Nigeria, an able and experienced health officer of the Colonial Medical Service, once saying to me that, for the prospective M.O.H. in the tropics one might do worse than recommend the study of Vivian Poore's "Essays on Rural Hygiene." Accordingly the student may be introduced to the subject in the following terms:—

"The indiscriminate scattering of human ordure on the surface soil is distinctly a more dangerous and offensive procedure in hot than in cold or temperate countries. For one thing, the deposits are much more likely to be infected, whether with the ova and larvæ of helminths, the cysts of *Entamœba histolytica*, the causative factors of diarrhœa, or the bacilli of enterica, dysentery, or cholera. For another, such virus-distributing agents as flies and dust are much more in evidence, while the habits of many native populations—for example, the way in which they go about barefoot, their methods of feeding and preparation of food, their disregard for general cleanliness—facilitate the transmission of disease. Yet again, in hot, moist climates at least, decomposition rapidly occurs, and though eventually it has the effect of rendering the excreta harmless they become at first, if in any bulk, exceedingly malodorous.

"The same is true in some respects when urine is voided in any quantity on the ground, and hence it is of the greatest importance to prevent soil pollution in the tropics." [1]

He will then be instructed as to latrines without receptacles and the ancient precepts and practice of Moses, first of known hygienists, and he will be told how methods must differ according to local conditions, for what is fit and proper in the Sudan is the very reverse in British Guiana. The danger of flies must be dinned into him, and the means of circumventing *Musca domestica* and its congeners in ways, some of which are the outcome of the Great War, fully detailed. Latrines, both private and public, with receptacles; complications introduced by the necessities of travel; native requirements, varying with creed and country; urinals of different kinds, all these somewhat unsavoury but essential matters require attention, and happy the lecturer who can impart a little chaste humour into the dry systems of conservancy. I think it must cheer and encourage a student to know that, during the war, an unlucky wight was seen with his ear close to the upper end of a funnel urinal which, in his ignorance and simplicity, he had mistaken for a listening post!

Incineration.

Methods of removal and disposal need not detain us beyond a reference to incinerators and the process of incineration. Too enthusiastic an advocacy of incineration will probably cause the lecturer to be dubbed an Ananias by one of his ex-students trying desperately to burn excreta under conditions which force him, in the words of an old but caustic dramatist,[2]

"to suffer wet damnation to run through 'em."

It is remarkable how opinions differ on the subject of the utility of incineration. Some appear to employ it successfully under all kinds of conditions, others have little use for it and magnify any nuisance which it may produce. There can be no doubt that a great deal depends on proper construction, adequate precautions, and an efficient technique. Given these desiderata, wonderfully good results may be obtained, even under trying circumstances. Like everything else in the practice of hygiene, incineration demands the exercise of common sense, attention to detail, and careful supervision.

The collection, removal, and disposal of refuse is a section which can be made far from uninteresting and can be lightened by a few historical references. Thus Zanzibar of the present can be compared with the "Stinkibar" of Livingstone's days, while the evolution of methods of disposal from the crude dump to the scientific process on which the Beccari system depends can be handled in a manner sufficiently attractive. Incineration will again come to the fore, but in some ways the incineration of refuse is a different problem to the incineration of fæces. Both may, of course, be combined, and in this connexion a few words on stoking and stokers will not be out of place.

Disposal of Waste Water.

The student should be warned that in many parts of the tropics one of the most difficult problems he will be called upon to consider, if not to solve, is the disposal of waste water. I believe that one would not be far wrong in saying that sullage has sullied not a few health records. What with difficulties due to heavy rains, to clayey soil, to soap, to offensive matters as in the case of sugar factories and slaughter-houses, to the fouling of natural watercourses, and to decomposition, the task of dealing with waste waters is often the bane of a medical officer of health in a country where there are no convenient drains and sewers to hide it from the sight and smell of the public.

Still, there are ways of getting over most of the difficulties, and amongst them the student should be taught the value of the use of lime. Disinfection and disinfestation call for careful exposition. The rôle of the tropical sun as a deodorising and disinfecting agent, its desiccating effects in desert regions, its limitations, and the known records of its action on pathogenic micro-organisms both in soil and water may precede a lecture of the more customary type introducing physical and chemical agents and their application.

Disinfestation.

If the myth of terminal disinfection has been exploded in the case of the communicable diseases of temperate climates, still more may it be relegated to obscurity in lands where intense sunlight and the sun's heat, fresh air, and the free perflation of wind are readily obtainable and where soap and water and limewash are nearly as cheap as in Europe. In the tropics disinfestation is more important than disinfection, and time may profitably be spent in a consideration of the manifold methods in use for destroying vermin, employing that term in a broad sense. Foremost amongst the vermin comes the

[1] The Practice of Medicine in the Tropics. Edited by Byam and Archibald.

[2] Cyril Tourneur.

house-fly, and this ubiquitous insect must be faithfully followed, along preventive and destructive lines, from egg to imago.

Formerly lice did not greatly concern the tropical hygienist, at least as disease vectors, except in certain parts of British India and in subtropical countries, for louse-borne typhus was rare and relapsing fever was largely confined to the regions mentioned. The recent southerly advance of louse-carried spirochætosis in the northern half of Africa has, however, put a different complexion on affairs, and in countries like Darfur and the French Sudan, Senegal, Northern Nigeria, and the hinterland of the Gold Coast, health officers have had to fight the loathly louse as it was fought during the Great War. The mention of spirochætosis serves as a reminder that we must class ticks amongst our vermin, notably, of course, *Ornithodorus moubata*, the intermediate host of *Spirochæta duttoni*.

General Health Measures.

Here or elsewhere the question of ridding ships of rats, fleas, cockroaches, and other pests must be ventilated. Perhaps it is best to relegate it to a section which may conveniently have the general title "Health Measures," and in which, after brief accounts of the methods employed in combating such typical maladies as ankylostomiasis, schistosomiasis, cholera, dysentery and enteric fever, filariasis and malaria, leishmaniasis and phlebotomus fever, plague, sleeping sickness, small-pox, undulant fever, yellow fever and rabies, the lecturer should pass to the hygienic control of shipping and of pilgrims, of camps and plantations, of railways and caravan routes. Quarantine will form part of his theme, and he will expound international law as it affects this great question. To lighten his subject and to aid the student both in his memorising and in his understanding of the facts put before him the teacher may have recourse to literary excursions like the following alliterative jingle on the causes of enteric fever. I have already published it, but not in its latest form. Here it is: Careless contacts and convalescents, carrier cases (chiefly cooks), defective drains, doubtful dairies, dirty drinking water, the dust of dried dejecta, faultily-gutted fried fish, sewage-soaked shell-fish, soiled salads, and the repulsive regurgitation, dangerous droppings, and filthy feet of fæcal-feeding flies fouling food.

In connexion with malaria it is important, if possible, to give a little instruction on the sanitary engineering sides, for both minor and major works of "bonification," as they term it in Italy, have an important bearing on malaria control, and the health officer should be in a position to discuss such matters in an intelligent manner with the engineer.

The *hygiene of native labour* in the tropics will doubtless have been largely dealt with under the headings housing, food, and conservancy, but the subject is not easily exhausted, and, to cite one matter only which should not be forgotten, there is the prevention of pneumonia by guarding against chill. How frequently do coolies exchange the atmosphere of a hot sugar mill or negroes that of the warm, humid depths of a deep mine for comparatively cold evening air and suffer in consequence. The provision of sweaters, if their use can be enforced, is often of great value, but only occasionally do we find this cheap and simple measure in vogue.

Even with every refinement of hygiene death will reap his victims and so *disposal of the dead* is a subject which will occupy a few minutes. Something should be said about special methods employed by races inhabiting the tropics and, in addition, the student should be told how best to embalm a corpse, for nowadays it is by no means uncommon, particularly in American circles, to require the return of the deceased tourist, traveller, or man of business, and the remains must be transported in a hygienic state, otherwise there may be trouble in several directions.

Public Health Administration.

The course may suitably conclude with some remarks on public health administration and organisation in the tropics, though, if it is preferred, this may constitute the opening subject. Personally, I am inclined to think it comes best at the end when, from the knowledge he has gained, or at least from the facts put before him, the student is better able to appreciate the situation and to realise that the duties of a health officer in the tropics differ in many respects from those he has to perform, say, in England, and that various modifications are necessary both in the administration and the organisation of a public health department.

It is, of course, impossible to deal with all parts of the tropics from this standpoint, but there are certain difficulties and certain essentials common to all and, on these the lecturer, if he is wise, will concentrate. Above all things he should impress upon his hearers the value of trained and efficient sanitary inspectors, those links between the medical officer of health and the populace, those employees, worth their weight in gold if they are good, who deal with details and, in the tropics, more perhaps than anywhere else, everything depends on attention to details. The number of European sanitary inspectors must perforce be limited, and so the training of a native inspectorate in the principles and practice of hygiene becomes a duty which the health officer has to shoulder and which will, as a rule, well repay the time he devotes to it.

It is scarcely possible to deal in any way adequately with sanitary law as applied to tropical practice, but I think students should be advised to study the regulations in force in various countries. Especially should they consider ordinances relating to mosquito control and the milk-supply, for they will find that the proper wording of such ordinances is most important and that their advice will be sought on these points.

LENGTH OF COURSE.

Well, we have reached an end, and it will be asked, "How long should such a course occupy?" I believe it might with advantage extend over three months, but, as a rule, that will be found impossible, at least if it is combined with the instruction in tropical medicine which we have already considered. Here we devote about 35 hours to these subjects and spread the course over a period of three weeks. I admit this is not sufficient, but it does give the class a certain grounding in the subject, and by reading and museum work the students can supplement this instruction, though they will never get a proper grasp of it until they have been "through the mill," as we say, and learned, perhaps by sad, and certainly by useful, experience, how to adjust themselves to new conditions and how best they may serve in that high calling of which they must be both the exponents and the disciples.

LABORATORY WORK.

I have said nothing about public health laboratory work, the chemical analysis of water, food, sewage, and so forth. It is true that, in the tropics, the health officer may have himself to carry out any tests which he thinks should be performed for, save at large centres, there are not, as a rule, any public analysts. On the other hand, in many places chemical laboratories exist where such work can be done by a trained chemist who, as a rule, can perform it more efficiently than the medical officer. In the absence of the necessary chemical equipment the medical officer is powerless, and hence, in a course such as I have described, it would be futile to attempt to include a laboratory training in public health chemistry.

Where, however, men definitely intend to devote themselves to health work in the tropics, they should be in a position to understand the significance of an analyst's report, and will best be able so to do if they themselves have some familiarity with the methods of the chemical laboratory. Hence, if they have not been through the D.P.H. course, I think provision should be made for their instruction in certain aspects of public health chemistry and also in bacteriology from the hygienic standpoint. Indeed, this is more important than the chemistry, for tropical conditions

may modify bacteriological standards, as, for example, the *B. coli* test in water work. This laboratory training would seem to attain a greater importance now that the Colonial Office has decreed that the possession of the D.T.M. & H. will qualify a man to hold a health appointment in places and districts other than those where large populations are congregated.

Men intending to take up such appointments, or to devote themselves to public health work, should also be given some instruction in vital statistics and statistical methods, and should learn more about epidemiology than they can in the tropical medicine course.

It is no doubt impossible to attain perfection in teaching tropical hygiene outside the tropics, and it is difficult to find sufficient time to devote to it, but a measure of satisfaction may be attained, by teachers and students alike, if we act on the advice enshrined in the old saying from the Book of Tobit: "If thou hast much give plenteously; if thou hast little, do thy diligence gladly to give of that little."

ON THE COMPLICATIONS OF FRACTURES OF THE LONG BONES.

By C. H. FAGGE, F.R.C.S. Eng.,
SURGEON TO GUY'S HOSPITAL.

THE disabilities which may follow a simple fracture of a long bone may be grouped under the following headings:—

1. Those affecting the bone itself, in the main purely mechanical; they result from failure to restore alignment or to maintain an alignment once restored. Whether they be classed as mal-union or as non-union does not affect the thesis of this paper, which argues that a vast majority of such results are preventable, and attempts to show why they occur and the principles on which their prevention should be based.

2. Those involving the muscles. Incorrect alignment of the fragments or involvement of tendon beds by callus alters the mechanics of their pull. These disabilities are exactly correlated with those of group 1, and are therefore equally preventable. Ossification of muscles is a very rare complication which may occur after fracture of the lower end of the humerus in childhood; but as, in my experience, it is directly attributable to rough handling and early passive movements, it is equally preventable, though by a different method.

3. Those affecting adjacent joints. Some of these are mechanical and, when due to simple causes such as the involvement of a joint surface by a misplaced fragment or by callus, are in most cases preventable, either by careful reposition by open operation of the intra-articular fragment so that exuberant callus which will hamper normal movement is not thrown out, or by removal of such a fragment when, owing to its size, position, or comminution, replacement is not practicable. By far the most common, depreciating, and incurable of the joint complications is that commonly termed chronic traumatic osteo-arthritis, which most of us have been accustomed to regard as an inevitable sequel of some fractures, particularly those is the vicinity of joints, in the middle-aged or aged. Yet we know that similar arthritic changes occur universally before the age of 21 in the hip-joints of those patients who in infancy have been subjected to manipulative reposition for congenital dislocation. Realising that this can best be explained on a mechanical hypothesis, we may venture the opinion that traumatic arthritis will occur only when the mechanics of the part are altered by a fracture, which is usually in close proximity to the joint, and that the mechanics are altered because alignment is imperfect. If this be accepted, we are forced to the conclusion that the arthritis is at least in part due to faulty alignment and is therefore preventable. This argument must not be pressed too closely, for it is conceivable that interference with the nutrition of the joint surfaces, owing to the injury, may be a factor of importance; that such a trophic influence does exist is shown in the marked atrophy with absorption of lime salts which occurs uniformly in the smaller fragment of these fractures.

4. Those due to nerve involvement; these are relatively rare and in common practice only comprise dropped wrist, due to musculo-spiral injury with fracture of the humeral shaft, and ulnar paralysis with fracture of the inner humeral epicondyle. I do not propose to discuss these fully, but must most forcibly insist that such paralyses are not, as most text-books state, due to involvement of the nerve by callus, but are due to its actual injury at the time of the accident by the force which caused the fracture, and that their pathology is an interstitial bruising which in most cases will recover, and will certainly do so provided the nerve is put under conditions which favour its natural capacity for repair. As it is at present impossible for any neurologist to suggest, even in the vaguest terms, the anatomical degree of nerve injury which exists in such cases, the surgeon must protect himself by the only means at his disposal and ascertain by direct inspection what damage has been done to the nerve in every case in which there is the least doubt—which means in almost every case.

First Principles.

Any attempt to discuss in more detail the prevention of the disabilities which are due to the fracture itself drives us to discuss first principles. The causes of displacement are the force which produces the fracture, gravity, and muscular pull. For some years the writer, in common with most other surgeons who have allowed themselves to think on such matters, has been teaching that the chief cause of displacement is the force which produces the fracture, and that the pull of muscles which may chance to be on one or other side of the fracture is not, as stated in most text-books, a very important factor in displacement; although after the fracture has occurred the natural tone of all muscles round the bone undoubtedly causes overlapping, and an unbalanced muscle or group of muscles may affect displacement. This is a fundamental assertion which governs most of what follows. Whenever one can exactly ascertain the direction of the force which caused a fracture, one finds that the displacement exactly conforms to this and, as the direction of the force may vary, so the displacement in any given fracture is not uniform.

Again, in our earliest surgical infancy we learn that transverse fractures are due to direct violence. They usually are, yet in many cases of transverse fracture the patients assure us that the blow was not direct, and this is confirmed by the absence of local injury to soft parts. A force great enough to break a bone directly must cause very grave damage to soft parts; yet in many fractures which are almost transverse no local bruising exists and we are forced to the conclusion that such fractures are examples of very short spirals and are caused by torsion. This view is supported and its scope enlarged by G. F. Stebbing's [1] hypothesis that fractures through the base of the neck of the femur are not caused by direct violence, but by torsion. Every surgeon sees several transverse fractures a year in which it is impossible to imagine how a force could be applied directly to the bone at that spot so as to cause the fracture. Whether direct or indirect, however, the force which causes a fracture cannot be supposed to cease immediately the fracture has occurred; its continuance causes displacement, and the greater it is or the longer it acts the more wide will be the separation of the fragments. The gap between the displaced bone ends must be occupied by soft parts, which are second only to sepsis as a local cause for non-union. The presence of soft tissues between fragments has long been recognised by two signs—viz., the absence of bony crepitus and the failure to restore alignment by manipulation

under an anæsthetic. To these I wish to add a third—an appreciable gap between the fragments as seen on an X ray plate. In my experience a gap of ¼ inch or more means the intervention of soft parts and forebodes non-union. It seems probable that the influence of intervening muscle is relative. A thin layer must intervene in almost every fracture; why, therefore, non-union does not occur more often, or how the offending tissues are got rid of, we do not know, but we must admit that the intervention of soft parts of a certain thickness is a sure barrier to the laying down of internal callus by osteoblasts from the bone-marrow.

I well remember in 1912 being astonished that the Fracture Committee of the British Medical Association so readily accepted the conclusion of their small drafting subcommittee, of which I was a member, that "a good functional result depends exactly upon a good anatomical result"; I have been still more surprised that the profession in this country and in the United States have never questioned this principle. These sensations, however, are mild compared with my horror at the almost daily examples of complete failure to carry it into practice. The more I see of fractures the more I am convinced of its truth and, after 15 years' test of its value, I am forced to admit that nearly all the bad results which I deplore in my own practice are due to a lapse from its logical employment.

Most of what is written above particularly applies to fractures of the lower third of the tibia, for, as has long been known, the mechanical defects of deformities resulting from fractures of the leg are indifferently compensated. Ashhurst [2] offers as an explanation of this that it is the only segment of a limb where the joints which bound it above and below carry out similar movement on identical axes.*

Reduction on the X Ray Table.

Even in hospitals to which large medical schools are attached the value of inspection and reduction of fractures under an anæsthetic on the X ray table is entirely unappreciated. Its chief value to the surgeon lies in an ocular demonstration of the maximum displacement, which is at once ascertained by rotation of the limb first in one and then in the other direction; this may disclose a far greater deformity than is shown by the plates or films usually taken as a routine in the antero-posterior and lateral planes. Scarcely less important is the advantage to the patient gained by observing under the screen that precise position, checked in two planes at right angles to one another, in which deformity is reduced to the minimum; it may at the time be impossible or unwise to fix the limb in the optimum position, but if this is known it can be readily achieved at the selected time. No one can study on the screen the optimum position for reduction in any series of fractures for six months without discovering the fact that in no two consecutive examples of what are apparently similar fractures is correct alignment secured in exactly the same position. In other words, each individual displacement has an individual position in which reduction of deformity is secured. This is only what commonsense would suggest, yet text-books describe stereotyped positions for every fracture, and witnesses in legal actions give evidence that a definite position is necessary for satisfactory treatment. How can witnesses who have not seen the fracture on the screen before treatment express an opinion on the optimum position—i.e., the particular pose that will secure correct alignment for this particular displacement?

Early Operation.

If we fail under ideal conditions to reduce the deformity on the X ray table, a second attempt is made; if this fails, we must realise immediately that some kind of operative reduction is necessary, and it is at this point that so many who treat fractures fail to carry into effect the principle which they know to be true, and rely apparently on the occurrence of some miracle by which the bad anatomical result which they know to be present shall be converted into a good functional one. A recent ununited fracture is as a rule easy to reduce during the first three weeks by open operation; and within certain limits a perfect anatomical reduction can be guaranteed if operation is done within this period; an operation for the correction of an old malunited fracture is often one of the supreme trials of manipulative skill, physical endurance, patience, ingenuity, and self-control. The most obvious advantage of early operation is that before new bone has had time to form and round off the rough broken ends, each little irregularity can be exactly fitted into its original place, and no time is taken up in breaking down a partial union. The bone ends become smoothed down after about three weeks, but I have recently found the line of fracture absolutely unchanged in a young man after 11 weeks; this is most unusual, especially in the young. Another advantage of early operation is the prevention of bone atrophy, which always occurs in the compact tissue of the smaller fragment, and is especially marked in the aged or alcoholic. It is of secondary importance, but any surgeon who finds himself faced with an operation on such a bone will take care to eliminate the risk in another case, for it is shown on X ray plates.

The indication for operative treatment is the failure to obtain or maintain reduction of displacement by manipulation. The phrase "reduction of displacement" can be otherwise expressed as restoration of alignment; it means that the fragments must occupy their normal positions and relationship to one another. How far this is necessary to sound union and functional efficiency is unfortunately a matter of opinion. "Unfortunately" is written advisedly, for, while it is agreed that end-to-end apposition of at least 25 per cent. of the fractured surface is desirable for firm union and that errors of alignment and angulation are readily overcome as growth proceeds in the young, yet beyond this there is a wide margin between what is deemed satisfactory by one and what is regarded as essential by another. All my experience tends to demand a more perfect anatomical result, for often the X ray plate has not been taken in the plane of maximum deformity, and displacements tend to get worse rather than better, particularly in the old and particularly in the leg.

Varieties of Operative Treatment; their Indications and Limitations.

1. The simplest form of operative treatment is reduction by leverage through an open incision without the introduction of any internal splint. This is particularly applicable to the common supracondylar fracture of the lower end of the humerus in children, fractures of the radius at the adolescent level, and separation of the lower femoral and upper humeral epiphyses. Many writers talk of operations on fractures as if internal splinting were always essential; of all forms of operation simple reduction is the most universally applicable, and it is far too rarely employed. Its use must be limited to transverse fractures, particularly where only one of two parallel bones is fractured, the other acting as a splint; or to fractures so near joint surfaces that an internal splint is impracticable. An open wound is no bar to this method, and in fact extends its range of usefulness, for, as infection may be unavoidable when reposition has been secured by open reduction, it is safer to rely on external splinting for the maintenance of position than to introduce unabsorbable internal splints.

2. The removal of detached fragments is a confession of failure, which is obvious when a fracture of the humerus complicating a dislocation of the shoulder-joint necessitates excision of the head. It must be admitted, however, that this is occasionally the only

* The leg is the only segment of a limb where the joints at both extremities of the bone are hinge joints.

practical procedure, and that the results are sometimes better than those secured by more conservative measures. Failure is less obvious when a small articular fragment is seriously comminuted, as is seen in stub fractures of the head of the radius, when excision is the only means available until such time as a suitable glue can be used.

3. Absorbable internal splints in the form of bone-grafts, whether homogeneous or heterogeneous, have, in my opinion, a very small field of usefulness and one practically limited to bridging a gap where a bone deficiency exists. I hold it as a fundamental principle in their use that they should not be subjected to stress or strain and that they must be secured; if this be true, they provide no alternative to internal unabsorbable splints, which are usually a necessary reinforcement.

4. I see no reason why some surgeons prefer an unabsorbable ivory peg to wire, screws, plates, and other metal appliances, except a lack of confidence in their surgical cleanliness. If exact restoration of shape and complete immobilisation is desired, there is no method which secures it in anything like so certain a measure in most long bone fractures as the use of plates and screws. I find no tendency for screws to loosen save in the presence of sepsis, which is almost always introduced by the operator. Though some of my cases were operated on more than 20 years ago, I see no reason for a routine removal of plates except in open fractures. Comminution, multiple fractures, and the proximity of less than two inches of a joint are an absolute bar to the employment of intramedullary pegs; the same applies, though to a less degree, to plates, though, when the main fragments are fixed together with a long plate, smaller fragments can usually be pushed into place, where they will remain.

Sometimes the problem is lack of union—e.g., a fracture has been immobilised for some six weeks and there is no sign on manipulation of solidification of the fracture. My practice is to treat the limb for another six weeks by complete immobilisation in plaster; whenever possible the patient walks on crutches, and a Bier's bandage round the thigh may help. If after this period there is no union, operation is indicated. I think these cases should be classified as cases of delayed union, and I have a suspicion that the usual cause of this delay is a thin layer of soft tissue between the bone-ends which the osteoblasts of the medulla have difficulty in permeating.

Conclusion.

The thesis of these remarks is that most, if not all, of the disabilities resulting from fractures of long bones are due to mal-union, the result of incomplete correction of displacement; that these are in the main preventable, and that the correct treatment of mal-union is prophylaxis. It must, however, be admitted that the period in which complete correction of deformity is possible must occasionally be allowed to elapse without any endeavour having been made to correct, owing to the very serious condition of the patient; but, unfortunately, this is not the excuse for the majority of bad results which surgeons are called upon to correct.

THE SERUM TREATMENT OF SCARLET FEVER.

By J. A. SCOTT, M.D. Liverp., M.R.C.S. Eng., D.P.H.,

LATE RESIDENT MEDICAL OFFICER, CITY HOSPITAL NORTH, LIVERPOOL; ASSISTANT MEDICAL OFFICER, SURREY COUNTY COUNCIL.

The benefits of scarlatinal streptococcal antitoxic serum in the treatment of scarlet fever are generally recognised, and an attempt is here made to compare the course and complications of the disease in cases so treated, with its progress in cases receiving identical treatment with the exception of the serum. Case records of 150 serum-treated patients at the City Hospital North, Liverpool, over a period of 15 months from 1925–27, have been collected and the results analysed. The serum was not used as a routine measure, but only for the more pronounced cases. As most observers note that the response to antitoxin after the fourth day of the disease is but slight the series have been divided into two groups—119 cases receiving antitoxin before the fourth day, and 31 cases receiving it for the first time after the fourth day.

Dosage.—Concentrated scarlatinal streptococcal antitoxic serum was used in each case, 10 c.cm. being injected intramuscularly in the vastus externus muscle. 137 of the cases received the serum prepared by the Lister Institute, 10 that of Messrs. Parke, Davis and Co., and 3 that of Messrs. Burroughs Wellcome.

TABLE I.—*Comparison of Serum-treated Cases in 1926 with Cases in 1925 and 1926 Receiving Ordinary Treatment.*

—	Serum-treated cases.		All cases 150.	Control cases.	
	Serum on or before fourth day: 119 cases.	After fourth day: 31.		1925. 120 cases.	1926. 120 cases.
Before serum: controls on third day. Average temperature	101·9° F.	101·5° F.	101·8° F.	99·8° F.	99·6° F.
,, pulse-rate	136 per min.	133 per min.	135 per min.	119 per min.	118 per min.
,, respiration	26 ,,	25 ,,	26 ,,	23 ,,	23 ,,
24 hr. after serum controls from third to fourth day. ,, fall in temperature	2·3° F.	1·7° F.	2·1° F.	0·7° F.	0·85° F.
,, fall in pulse-rate	17 per min.	10 per min.	15 per min.	8 per min.	9 per min.

Relapses	—	—	—	1	6
Case mortality (per cent.)	—	—	1·3	2·5	—
Serum rashes (per cent.)	—	—	10	—	—

Dose of serum: 10 c.cm. of concentrated serum intramuscularly. 11 per cent. of all cases received two or more injections.

and Co. 11 per cent. of the cases received two or more injections, the maximum number given being six injections.

Control.

The selection of an adequate control series was rather difficult, as all the more serious cases from November, 1925, were treated by antitoxin. Owing to seasonal variation in the incidence and virulence of the disease it was thought best to adopt two series of controls, each over a full year, one from the 1925 cases before the serum was used and one from the mild, non-serum treated cases of 1926. Accordingly the first ten cases admitted to the hospital in each month in 1925 and in 1926 were grouped and analysed, the results being shown parallel with those of the serum-treated group in Table I. As in the latter group the average day of serum administration in those cases treated before the fourth day was the third, the average temperature, pulse, and respiration rate on this and on the fourth have been noted in the control groups and the fall in each in the 24 hours tabulated for comparison with that in the serum-treated groups.

The classification of the nature of the disease and the age-distribution of cases are shown in Tables II. and III. respectively. The age-distribution is approximately the same in all groups. The type of disease in the 1925 control-group, during 11 months of which no serum was used, was more severe than that in the 1926 controls. Table I. shows that the fall in temperature, pulse-rate, and respiration-rate in the serum-treated cases is about twice that in the controls from the third to the fourth day, while the complications in the former group, except for suppurative otitis media and arthritis, are much the same as in the mild 1926 group and less than in the 1925 group. It is of interest to note that five cases of arthritis in the serum-treated group arose about the tenth day; though unassociated with a rash, they may be a manifestation of the serum administration rather than a complication of the disease.

Together with the fall in temperature and pulse-rate after the administration of serum, the patients exhibited marked subjective improvement and the pain and discomfort of anginoid conditions of the throat were greatly relieved. In 12 of the treated cases a profuse rhinorrhœa ceased very dramatically within 48 hours. The benefits of serum, in the dose employed in the present series, are less marked if given after the fourth day, but a temporary alleviation of symptoms was often noticed.

The good effects of the treatment are to some extent reflected in the mortality figures of scarlet fever admissions to hospital, which were 1·88 per cent. in 1925 and 0·75 per cent. in 1926.

TABLE II.—*Classification of Nature of Disease.*

—	Septic.	Severe.	Mod. severe.	Moderate.	Mild.
	Per cent.				
150 serum-treated cases ..	8	22	39	18	13
120 control cases—1925 ..	3	6	—	28	63
120 control cases—1926 ..	—	—	—	18	82

TABLE III.—*Age-distribution of Cases.*

—	0–5 yrs.	5–15 yrs.	Over 15 yrs.
	Per cent.		
150 serum-treated cases ..	32	57	11
120 control cases—1925 ..	30	59	11
120 control cases—1926 ..	30	66	4

Conclusions.

1. Scarlatinal streptococcal antitoxic serum, given early in the disease, causes a fall in the temperature, pulse, and respiration rates, relieves the subjective symptoms, and prevents the development of complications. 2. In the doses employed in this series no immediate benefits were noted in cases treated after the fourth day of the disease.

I am greatly indebted to Dr. R. I. Richardson, visiting physician, City Hospital North, for permission to make use of the hospital material and records, and also for much clinical advice and help.

MINOR TUBERCULOSIS.*

BY E. WARD, M.D. CAMB., F.R.C.S. ENG.,
TUBERCULOSIS OFFICER, SOUTH DEVON.

Two decades of collective effort to eliminate tuberculosis justifies an attempt to review our conception of the disease.

The Victorian conception of tuberculosis may be summarised as: "A fatal disease; when recovery ensues the diagnosis should be revised." Then came what might be called the Edwardian conception: "A widespread disease as a pathological finding, but always dangerous, and often fatal, when causing symptoms." I would like to formulate a Georgian conception: "A widespread disease terminating usually in uneventful recovery among the highly resistant majority of the population, but dangerous to a minority with low resistance."

Minor tuberculosis, that is, tuberculosis as manifested in the highly resistant majority, occurs at one time or another in the lives of 40 per cent. of human beings. In busy private practice I often noted patients with one or two symptoms suggesting tuberculosis: a cough, wasting, lassitude, "run down," weakness, chest pains, or sometimes hæmoptysis. Under observation the symptoms almost always passed off, but rarely an individual patient developed typical phthisis pulmonalis. As tuberculosis officer, following in their homes the lives of some thousands of contacts, I am convinced that this minor tuberculosis is very real, and that recognition of its existence will clarify our ideas on tuberculosis, smooth out some differences of opinion among able observers, and perhaps provide a key to the whole problem.

A few instances may be given:—

CASE 1.—During the spring of 1916 a medical man of 38 was rejected for war service because an examining board detected pulmonary tuberculosis. The patient was tall and thin with sloping shoulders, the type described as "homo popleus." He had worked hard during the winter, and had suffered the last few months from a troublesome cough. His weight was 3–4 lb. below normal, and he had lately found work more tiring than before. There was a slight atrophy of the right upper trapezius with perceptible drooping of the shoulder. Dullness, diminished expansion, and a few crepitations were noticed at the right apex, or a few crepitations were also heard on the left side. The patient did not cease work, but took a few commonsense precautions, and has continued with no recognisable symptoms since the summer of 1916.

CASE 2.—A medical man of 51 was seen in the summer of 1918. He had felt ill and run down lately, and his habitual morning cough had become worse; there had also been fugitive chest pains. Ten days previously there had been a morning hæmoptysis of 3 oz. The patient was pale, thin, and rather haggard-looking; a few physical signs were present at the left apex, and dullness, with some pleuritic crepitations, at the right base. I pressed him to take a holiday; he refused, but became much more careful than in the past. At 59 he continues frail, but there have been no further symptoms of importance, and he is still in active practice.

CASE 3.—A doctor's daughter and lady dispenser, aged 23, came for advice because she had expectorated a mouthful of blood; there was also a dry cough, occasionally troublesome. The patient's father had died from tuberculosis, and

* From a paper read before the Plymouth Medical Society.

a few years previously she had nursed and slept in the same room with a cousin who subsequently died of phthisis. The patient was active, frail, and thin, with a slight stoop; there was dullness at the apex of the right lower lobe. It was difficult to decide what advice to give; she was allowed to continue work under observation and an improved régime. Four years later she married, and remains well after 12 years of married life, during which she has borne three children.

CASE 4.—A school teacher, aged 26, had signs and symptoms suggestive of tuberculosis, and the sputum, on the one occasion that it was obtainable, contained tubercle bacilli. A short holiday and a few adjustments were the only treatment. Fourteen years later she continued to work regularly without symptoms.

Among children tuberculous manifestations are also common—e.g., failure to thrive, prolonged pyrexia, gastric troubles, and sometimes cough. The following history, sometimes heard in chronic adult pulmonary tuberculosis, illustrates the difficulties which occasionally arise: (*a*) as a child prolonged pyrexia labelled typhoid, rheumatic fever, or influenza; (*b*) from 15 to 20, tonsils removed for bad health, perhaps more than once; (*c*) about 22, an attack of pleurisy; (*d*) at 24, appendicectomy; (*e*) at 28, all teeth removed, and perhaps a course of vaccine therapy; (*f*) at 32, phthisis diagnosed.

Minor Tuberculosis and the Work of the General Practitioner.

The suggestion that the great majority of tuberculous lesions discovered at autopsy have given rise to symptoms during life is borne out by experience in other diseases. A large percentage of autopsies reveal gall-stones; it was once thought that most of these had been symptomless, but now that we are beginning to recognise the symptoms they may cause, it seems probable that very few cases, if any, are really symptomless. They constitute a proportion of those dyspepsias which it is the lot of general practitioners to treat. The duodenal ulcer which perforates without previous symptoms is also becoming a great rarity now that the symptomatology is better known.

There is a tendency for symptoms to go unrecorded, and sometimes unnoticed, when their cause is unrecognised. The study and coördination of such symptoms is essentially the scientific province of the general practitioner.

The existence of minor tuberculosis is increasingly recognised. Some speak of latent tuberculosis, but this does not seem the best word when symptoms are present. Others call the condition a tuberculous infection, as opposed to tuberculous disease, but the difference between the two is of degree only. To me "minor tuberculosis" seems a better phrase.

Once the condition is fully recognised it must modify our work and teaching in many directions. Statistics are incomparable when one observer includes minor cases and the other only the graver ones. In conjugal tuberculosis, for instance, if minor disease is included, an infection will be found in the majority of cases, but if our attention is limited to major cases, occurring in the 2 per cent. of the population who have low resistance, conjugal infection becomes rare. Similar remarks would apply to any estimate of infectivity in tuberculosis, and to sanatorium statistics. If the patients sent to sanatoria are always to be "early" cases a number of minor cases will be included, and these could quite well be treated at home.

For practical purposes sputum-positive cases are all major, so that statistics based on sputum tests are comparable; but these constitute only a portion of the tuberculosis literature.

Allergy and Pneumococcal Infections.

Besides minor disease, two other factors modify our conception of tuberculosis: allergy and other pulmonary infections.

Koch's phenomenon is well known. A guinea-pig infected for the first time with tubercle bacilli may die of the disease, but show no local signs at the site of inoculation. If, however, after a sublethal dose of bacilli, a second injection is given, there is a violent local reaction which often results in sloughing. The animal is said to be in a state of allergy. Tulloch and Munro have shown that by thus sensitising a guinea-pig we may simulate the fibro-caseous phthisis of human beings. It seems likely that the easily recognised, typical phthisis of man is the result of some such sensitisation, the pathological and clinical pictures depending largely on the degree of allergy. Therapeutically just the right amount of allergy should be our aim, so that there will be a reaction at the site of infection, but no breaking down.

Inseparably connected with the tuberculosis problem are other forms of pulmonitis, especially pneumococcal infections. Tuberculosis disposes to catarrhal infections and these dispose to tuberculosis. This, indeed, is the greatest difficulty in diagnosis. We read strongly worded opinions that patients with bronchitis must not be called tuberculous, and opposing views are also held. A way out might be found by speaking of "catarrhal pulmonitis" and "tuberculo-catarrhal pulmonitis." In the diagnosis of pulmonary tuberculosis the chief erroneous tendencies are, on the one hand, in patients only slightly ill to diagnose minor tuberculosis as something else, and, at the other end of the scale, in patients obviously ill, to diagnose chronic pneumococcal infections as tuberculous.

A LOCALISED OUTBREAK OF BACILLARY DYSENTERY IN SMETHWICK.

BY A. G. MILLOTT SEVERN, M.A. CAMB., M.D. BRUX., D.P.H.,
DEPUTY MEDICAL OFFICER OF HEALTH, COUNTY BOROUGH OF SMETHWICK;
AND
EWART W. EVANS, M.R.C.S. ENG.

DYSENTERY has not been a common disease in England since public health principles have been widely applied, but in the seventeenth and eighteenth centuries the "bloody flux" was one of the formidable diseases of this country, as is shown, for example, by the Bills of Mortality of that period for the City of London. After the war it was thought that demobilised soldiers from abroad would reintroduce infection, and dysentery was made compulsorily notifiable under the Public Health (Pneumonia, Malaria, Dysentery, &c.) Regulations, 1919, in order that the authorities might have adequate control over these diseases, and give prompt assistance in combating possible epidemics. This policy has proved a wise one, and several epidemics, small and large, have been investigated and checked. The number of notified cases of dysentery and deaths registered since the adoption of compulsory notification in England and Wales is as follows:—

Year.	Cases notified.	Deaths registered.			
		Total.	Bacillary.	Amœbic.	Other or unspecified.
1919	1638	435	?	?	?
1920	1169	254	?	?	?
1921	1193	261	17	11	233
1922	757	216	21	10	185
1923	458	149	12	13	124
1924	356	130	13	8	109
1925	293	135	13	11	111
1926	486	142	11	14	117

It will be seen that the numbers have diminished considerably during the last four years. The type has, in the great majority of cases, been bacillary, although the above table does not sufficiently indicate this. Amœbic dysentery has apparently never prevailed much in England; the climate or other conditions, for some obscure reason, are unfavourable to the propagation of this type, although healthy "carriers" of *Entamœba histolytica* are not by any means uncommon. Since the war several outbreaks of dysentery in England and Wales have been

nvestigated by medical officers of the Ministry of Health, and very complete records of their findings have been published in official reports.

Bacillary dysentery, before the war, was largely confined in this country to circumscribed outbreaks n lunatic asylums and similar institutions.

The interest of the outbreak here described lies in he completeness with which it was possible to trace he ætiology and correlate the various findings, and n certain individual features. No instance of lysentery had been reported in Smethwick since 1924, when one isolated case was notified, and since 1919 only 20 cases are known to have occurred ocally amongst a population of over 75,000.

The outbreak which occurred at the end of July nd the beginning of August, 1927, was limited to he families residing on the first and second floors f a tenement house in Smethwick. The symptoms, ncluding pyrexia and the frequent passage of stools ontaining blood and mucus, were typical of acute acillary dysentery. There were ten cases, the first eing a child, attacked on July 22nd. The others ollowed rapidly, and all had similar symptoms, lthough they varied in degree; at least four of the atients were severely ill. There was no evidence uggesting case-to-case infection, and there were no eaths.

When the cases were reported to the local public ealth department every probable source of infection as investigated. The only common factor was the ater-supply. The water consumed by all the ufferers on these premises had been taken from the athroom tap connected with the hot-water system, nd the water had not been heated for many months. his water, derived originally from the main town upply, was fed into an uncovered iron tank through ball-tap valve and was passed through a cast-iron oiler and a closed iron cistern before reaching the ap from which it was drawn. The connecting pipes ere made of galvanised iron. This supply had been sed for some months because the main water tap as out of order. It was evident that the open tank ad become specifically contaminated. The families esiding on the ground floor used water from a eparate tap connected directly with the main, and ll escaped dysentery. The infection was confined to he women and children in the house; presumably he men took their liquid refreshment at work or utside their homes. One of the men volunteered the tatement that he had never drunk the water from his tap as he always thought it had an unpleasant aste; he escaped infection.

Other lines of investigation and possible sources of nfection were not overlooked, but there was no vidence that they had any connexion with the utbreak.

After a sample of the contents had been taken, he use of the water from the open tank system was rohibited; the tank and cistern were flooded with isinfectant, and no further case of dysentery occurred.

The bacteriological investigations were undertaken y Prof. C. J. Lewis, director of the public health aboratory of Birmingham University. Specimens of eces from five of the patients were cultured, and a ysentery bacillus of the Flexner type was isolated om each. Blood specimens from the earlier cases ere examined for the Widal reaction, and reported egative for *Bacillus typhosus* and *paratyphosus*. The lood serum of one of the patients was tested against ne organism previously isolated from her own eces, and agglutinated in a dilution of 1 in 40.

The residuum of water and deposit from the open ank was examined and intestinal bacilli of the oliform type and spores of *Bacillus enteritidis porogenes* were found, thus demonstrating previous ecal contamination. Actual dysentery bacilli were ot isolated.

Our search was now directed towards the primary carrier," and inquiry showed that a member of ne of the affected families was an ex-soldier who had erved in the Near East during the war and who ad been in hospital suffering from dysentery and malaria in Salonica in 1918. Although he was still liable to attacks of malaria, he had not, as far as he was aware, had any recurrence of diarrhœal disease since his discharge from the army and return to England, nor did he contract dysentery during this epidemic. His blood serum was tested for agglutination against several organisms, and proved negative for the typhoid group, but positive in significant dilutions for one of the types of bacillus which had been previously isolated from the fæces of the patients. The agglutinins produced by his antityphoid inoculations during the war had thus disappeared. His cultivated fæces were at first negative for cysts or pathogenic organisms, but from a second fæcal specimen obtained a few days later, and plated on MacConkey's agar medium, a colony of non-lactose fermenters was isolated, and gave the cultural reactions of the *Bacillus dysenteriæ* of the Flexner type. This may be regarded as a satisfactory result considering the well-known intermittency of excretion of bacilli among dysentery "carriers."

Thus the chain of infection appears to have been traced completely, and little doubt is left that the disease was spread through the agency of the tank water, which had in turn been specifically infected from the dysentery "carrier" living in the house. It was obviously not possible to determine the exact manner in which the tank water became contaminated from the "carrier," but the only available water-closet inside the house, used by all the families concerned, was in a dirty and neglected condition. Rats had been seen, and flies and mice were prevalent on the premises, and would suffice to provide adequate transport for the infective fæcal material between the water-closet and the unprotected open tank.

Our reason for publishing a short summary of this outbreak of bacillary dysentery is to call attention to the danger of using for drinking purposes water derived from the usual type of hot-water system so frequently installed in private houses and commonly regarded as innocuous.

One other noteworthy point is the length of time, in this case nearly ten years, during which a "carrier" of dysentery may remain a potential source of infection to others in his immediate surroundings.

THE EFFECT OF INTRAVENOUS AND INTRAMUSCULAR INOCULATIONS OF NOVASUROL IN RABBITS.

By P. LAZARUS-BARLOW, M.D. Camb.,
ASSISTANT BACTERIOLOGIST, METROPOLITAN ASYLUMS BOARD, QUEEN MARY'S HOSPITAL FOR CHILDREN.

Novasurol is an organic mercury compound and consists of a double combination of the sodium salt of oxymercurio-o-chlorphenoxylacetic acid with diethyl-malonyl-urea. It is claimed to be a powerful diuretic, absolutely free from irritant properties, and therefore equally suitable for intravenous and intramuscular injection, especially in cases of morbus cordis associated with dropsy.

At the request of one of my colleagues four rabbits were inoculated intravenously and intramuscularly with various doses of the drug; the histological findings seem worthy of report. The inoculations were made as follows:—

A.—0·02 c.cm. novasurol intravenously on alternate days for three doses and the animal killed three days after the last inoculation.

B.—0·02 c.cm. novasurol intramuscularly into the thigh on alternate days for three doses and the animal killed three days after the last inoculation.

C.—0·02 c.cm. novasurol intravenously—

0·03	c.cm.	,, ,,	three days later.
0·05	c.cm.	,, ,,	two days later.
0·1	c.cm.	,, ,,	two days later.
0·3	c.cm.	,, ,,	three days later.
0·7	c.cm.	,, ,,	two days later.

D.—Received the same quantities as C, with the same intervals between doses, the inoculations being made into the muscles of the thigh. Rabbits C and D were killed two days after the last inoculation.

The doses given to A and B were considered to be approximately equal, weight for weight, to the dose for a child. The larger doses in the case of C and D were given to ascertain if any lesions that might be produced in A and B could be intensified.

Histological examinations were made from the liver and kidney in all four cases, and from the muscles at the sites of inoculation in the case of B and D, and showed the following :—

A.—Liver : A considerable degree of cloudy swelling throughout, the outlines of the cells for the most part being quite obliterated ; this change is more marked in the centres of the lobules. The nuclei stain poorly. Blood-vessels and capillary spaces congested throughout. Kidney : Considerable cloudy swelling throughout both the convoluted and straight tubules ; in many cases the cells are completely separated from the basement membrane. The organ is congested throughout.

B.—Liver : Some cloudy swelling ; great distension of the capillary spaces, many of which are filled with blood. Vessels congested. Kidney : Cloudy swelling throughout ; in many places the lumen of the tubules is completely filled with finely granular cytoplasmic debris. In places there is great separation of the tubules. The organ is congested and many glomeruli appear somewhat disintegrated. Muscle : Along the track of the needle there is considerable congestion and a well-marked fibroblastic reaction with numerous giant cells ; muscle-fibres are almost entirely absent. On either side of the needle track the muscle is degenerated, the nuclei having disappeared and the fibres being hyaline in appearance.

C.—Liver : Cloudy swelling with slight fatty degeneration in places ; vessels and capillary spaces congested throughout. Kidney : Glomeruli congested, and the majority show some vacuolation. Large numbers of convoluted tubules show either absolute necrosis or very marked cloudy swelling ; a few appear fairly healthy. Many are filled with a hyaline substance. The straight tubules appear relatively healthy, some show cloudy swelling and degeneration, some contain a hyaline substance.

D.—Liver : Marked degeneration. Throughout the section the cell walls of the liver cells form an open network, in the meshes of which lie very poorly staining nuclei and some granular cytoplasmic debris. Kidney : Some glomerular congestion. Marked cloudy swelling of the convoluted tubules, but no areas of necrosis. The straight tubules show great destruction of cytoplasm, in many cases the nuclei lying free on the basement membrane. Capillaries rather congested. Muscle : There is an extensive area of completely necrosed muscle, the nuclei having disappeared. Large streaks of hæmorrhage are present, apparently along the tracks of the needle. At the periphery of the necrotic area is a well-marked inflammatory reaction, and in places considerable fibroblastic infiltration.

These sections show that novasurol may have a very profound action on the healthy liver and kidneys of rabbits ; since in chronic heart disease the liver and kidneys are affected to a greater or less degree this fact may be of importance. In chronic heart disease the central portions of the lobules of the liver are most severely affected by the back pressure, and the experiments show that this is the portion of the liver on which the drug exerts its greatest effect. It would seem advisable, therefore, that in cases of long-standing heart disease where there is a possibility of damage to the liver through back pressure, the dose of novasurol should be much reduced. In such cases the kidneys also may become damaged, and the experiments suggest that if there be any nephritis or albuminuria the drug is contra-indicated, or at least should be given only in very small doses. The drug appears to have considerable irritant properties ; no ill-effects, however, were observed at the sites of inoculation of the intravenous doses. It thus appears, as far as can be judged from animal experiments, that the intravenous route is superior to the intramuscular.

Summary.

Animal experiments suggest that in cases of long-standing heart disease the dose of novasurol should be considerably reduced, and that intravenous inoculation is more advisable than intramuscular.

Clinical and Laboratory Notes.

A CASE OF SPASMODIC AURICULAR FIBRILLATION AND BRONCHO-PNEUMONIA COMPLICATING SEPSIS IN THE PUERPERIUM

BY JAMES A. KERR, B.Sc., M.B. GLASG., D.P.H.,
SECOND ASSISTANT MEDICAL OFFICER, MONSALL HOSPITAL, MANCHESTER.

THIS case is considered worthy of record for several reasons. It is one with which any general practitioner might suddenly be confronted, and with which he might have to deal without a specialist opinion and the primary treatment was carried out at a hospital not equipped with special cardiological apparatus, the writer having no special experience in the newer cardiology. The prognosis was very poor. Leyland Robinson [1] gives 13 deaths out of 16 cases of auricular fibrillation following parturition and G. J. Langley [2] gives one death out of three cases, while the other two responded badly. Many other authorities quote statistics, but do not fully differentiate the types of cardiac case. A search of the literature revealed no case of recovery of severe auricular fibrillation when complicated by broncho-pneumonia. Lastly, the case seems to afford a convincing argument in favour of large doses of digitalis in the treatment of auricular fibrillation. Although the patient never had any blood infection she was seriously ill from pelvic sepsis, and hæmolytic streptococci were found in her cervical canal. In addition, there had been a breakdown in the cardiac mechanism on at least one previous occasion auricular fibrillation had been present for at least four days before the treatment was initiated, and there was a fairly marked degree of broncho-pneumonia. It is therefore all the more remarkable that, within 12 hours of the administration of this large dose fibrillation ceased, and no apparent cardiac irregularity could be detected until 12 hours afterwards although the pulse-rate was taken at the apex at half-hourly intervals during most of that period.

The patient, aged 41, was sent into Monsall Hospital on March 5th, 1927, by Dr. L. J. Shaw with a diagnosis of puerperal pyrexia. She had had an apparently normal confinement on Feb. 23rd, ten days previously. She had had auricular fibrillation and broncho-pneumonia for two days before admission. There had been three previous confinements and two miscarriages. There was also a history of rheumatic fever in 1902 and 1910, and of a breakdown in the cardiac mechanism with associated œdema following the previous confinement.

Condition on Admission.—The patient was extremely cyanotic and collapsed, with a typical irregular pulse. She had a troublesome cough with frothy mucopurulent sputum, but there was no hæmoptysis. There were definite signs of broncho-pneumonia at both bases, especially on the left side. The possibility of pulmonary infarcts was ruled out, as the two lungs appeared to be symmetrically affected. There was a definite pleuritic friction rub in front of the area of the apex impulse. The apex-beat was just outside the nipple line and the first sound was completely replaced by a murmur, while there was also a well-marked diastolic murmur. There was a very definite increase in hepatic dullness. The urinary output was extremely low, with slight albuminuria. There was marked tenderness in the lower abdomen. The uterus was fairly well involuted, but with marked bilateral parametritic infiltration. There was a little sanious and slightly offensive leucorrhœa.

On the following day there was a definite improvement in the rhythm of the pulse, but the rate remained irregular. A culture from the cervical canal revealed hæmolytic streptococci, but a blood culture proved sterile. On March 7th the condition of the patient was precarious. It was decided to use Eggleston's method of massive digitalis administration,[3] the large dose being indicated by

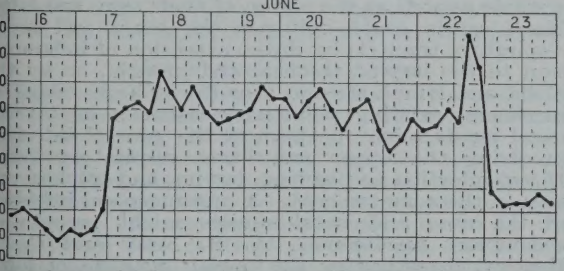
[1] THE LANCET, 1927, i., 170.
[2] Brit. Med. Jour., 1927, i., 1043.
[3] Jour. Amer. Med. Assoc., 1920, lxxiv., 974.

he complete cardiac breakdown with orthopnœa and other omplications. The basis of calculations of dosage is ·15 c.cm. of the tincture of digitalis per pound of body-veight. Unfortunately, the body-weight and the allowance or previous dosage (approximately gr. 1/60 digitalin very four hours for three days) could only be roughly stimated. Fortunately the early toxic symptom of vomiting ould be relied on to protect the patient from an over-lose. After some trepidation 250 minims of a tincture of ligitalis of known potency was administered, without ubsequent vomiting.

On the following day the patient was much more comfort-ble, the pulse varied between 110 and 90, and was 100 per ent. improved in volume. There was only occasional ardiac irregularity (two or three irregular beats followed y 10 to 12 regular ones) and there was a definite typical ough, presystolic murmur. The pleurisy was not spreading. nd the broncho-pneumonia improved on the right side, ut remained about the same on the left. The sputum became ummular and less frothy. The urinary output increased rom 25–50 oz.; there was still a good deal of offensive eucorrhœa.

On March 9th the patient's colour had improved markedly, nd the pulse was of excellent volume, and only very ccasionally irregular. The presystolic murmur was not early so obvious. The broncho-pneumonia on the right ide had apparently gone, while the left lung was much learer. There was no trace of any pleurisy. The cough was ess troublesome and the sputum still nummular but less rothy. The urine was clear, but there was still a fair mount of sanous offensive leucorrhœa.

On March 11th the pulse was absolutely regular, with a ate of about 70. There was still a small patch of tubular reathing over the left lower lobe posteriorly. On larch 15th, one week after the administration of the dose, was realised that its beneficial effect had reached a naximum, but, as the pulse remained regular at 70–80 and ne urinary output remained about 66–70 oz., the patient



Pulse chart including the period June 17th–23rd during which the patient had auricular fibrillation.

as allowed up, without ill-effects. Five days later the ulse became slightly irregular, and the patient was put n tinct. digital. ℥ v. t.d.s. This was increased on larch 22nd to ℥ xv. t.d.s. During this period the inflamma-ry conditions in the pelvis were gradually settling down, nd on March 30th the offensive leucorrhœa ceased.

On April 8th the patient was discharged. She had a ell-marked presystolic murmur, and the apex-beat was the nipple line. The pulse-rate was between 80 and 100, t absolutely regular, and the patient's exercise tolerance as better than it had been for the last 15 years. The elvic organs were healthy, except that the uterus was alled over to one side of the vertical axis. The lungs ppeared normal, but the liver still extended down to near ne umbilicus, being partly enlarged and partly ptosed. igitalis, once utilised, must be continued,[4] so the patient as referred to the cardiac clinic at Ancoats Hospital, here Dr. G. J. Langley found mitral stenosis, stage II., ith definite murmur and thrill, but without fibrillation. n electrocardiogram taken on April 8th shows normal ythm of the heart with the auricular waves clearly marked nd the spacing regular.

One month later she was much worse, being cyanosed and yspnœic. Her auricle was fibrillating at 120 per minute nd was grossly irregular. A full diastolic rumble was still resent, but no presystolic thrill could be detected. She as admitted on May 31st for observation. Her heart mained regular until the period for which the temperature hart is shown, when her auricular fibrillation became asmodic in type. She had a sudden onset of auricular rillation at 10 A.M. on June 17th, and four hours later er pulse had risen to 120. In an electrocardiogram taken on this day the auricular waves have disappeared, the rhythm has become completely irregular, the ventricular complexes are unequal in size, and the usual undulations of fibrillation are visible in lead III. She remained in this condition until June 22nd at 10 P.M., when 13 tablets, each equivalent to 1 c.cm. of tincture of digitalis, were administered. The rate fell from 150 (after atropine release) to 72, at 4 A.M. on June 23rd, after which it remained regular until discharge (see chart).

Digitalis, although fully competent to control auricular fibrillation, has no power to reinstate a normal rhythm, and the accompanying chart gives the explanation, the onset and offset of the tachy-cardia due to auricular fibrillation being absolutely sudden and spontaneous.

In conclusion, I wish to express my indebtedness to Dr. D. Sage Sutherland, medical superintendent, Monsall Hospital, Manchester, for permission to publish this case; and to Dr. G. J. Langley, physician to Ancoats Hospital, for permission to utilise his notes of the subsequent history of the case.

A CASE OF NERVE PALSY.

By NATHAN WALSH, M.B., CH.B. LEEDS,
PUBLIC VACCINATION AND DISTRICT MEDICAL OFFICER, SCARBOROUGH UNION.

THE following case is, I think, worthy of record.

A labourer, aged 32, gave a history of pain in the outer side of the left leg occurring during a game of football, but not referred to any definite injury during the game. He says his "knee gave way," and this was followed by a dull pain which was not severe. He finished the game and walked home without much discomfort. The pain became worse and he was seen the following day.

When examined, the outer side of the left leg, about 2 inches below the head of the fibula, was red, swollen, stony hard, and tender. Pain was also present on the dorsum of the foot. There was no sign of bone injury. He was unable to dorsiflex his ankle or to abduct his foot. He thus had "foot-drop," the muscles chiefly affected being the peronei and extensor digitorum longus. There was no wasting and no loss of sensation. The X ray showed no abnormality. The only diagnosis was palsy of the anterior tibial nerve, due to rupture of fibres either of the peroneus longus or extensor digitorum longus, with a deep hæmatoma compressing the nerve, either as it passes between the head of the fibula and the peroneus longus or as it passes beneath the extensor digitorum longus. Under massage and electrical treatment he is slowly improving. It is surprising that he had so little pain with such a marked lesion.

My thanks are due to Dr. J. R. Dick, hon. surgeon to Scarborough Hospital, for the X ray examination.

A CASE OF
CYSTIC PNEUMATOSIS OF THE BOWEL.

By J. SILVERSTONE, M.B. LOND., M.R.C.S. ENG.,
SENIOR HOUSE SURGEON, NORTH STAFFORDSHIRE ROYAL INFIRMARY.

THIS condition was the subject of the presidential address delivered by Mr. Cyril A. R. Nitch before the Section of Surgery of the Royal Society of Medicine in November, 1923.[1] The disease is analogous to intestinal emphysema of swine. In these animals it is the rectum, jejunum, and mesentery which are most commonly affected, and the disease is seen chiefly on the mesenteric border. In pigs it is always associated with an intestinal catarrh. In man the disease is rare, only about 85 cases having been previously recorded. It is associated with constipation, and usually there is an organic stricture of some portion of the intestinal tract. It has invariably been discovered either at operation or at post-mortem examinations. The commonest coexistent lesion is either gastric or duodenal ulcer, and of these about 83 per cent. have shown stenosis.

[1] British Journal of Surgery, 1924, xi., 714.

Males are affected in the ratio of three to one, and the ages range between 13 and 60 years. It is seen most often in the ileum, near its termination on the anti-mesenteric border, but it may affect any other part of the intestinal tract, most rarely the rectum, duodenum, and appendix. The large bowel is frequently involved, the disease stopping at the splenic flexure. As a rule, the bowel is affected for a considerable distance, but the disease may occur in isolated groups separated by normal bowel. The cysts are usually sessile, but may be pedunculated; they are situated in the subserous and submucous layers and are seldom seen either in the muscular coat or mucosa. They rarely communicate with the lumen of the bowel or with each other.

Histologically, there is an endothelial lining containing a number of giant cells (suggesting chronicity). Small round cells and other signs of inflammation are absent. There is a chronic hyperplastic endolymphangitis, which suggests that the condition is one of gas-containing spaces formed in the lymphatics, rather than clefts in the connective tissue.

Cultures from fresh specimens have been negative. The gas consists of a large percentage of nitrogen, as well as oxygen, carbon dioxide, and a little hydrogen. Second operations have shown that the cysts disappear spontaneously, leaving a typical cicatrix.

The theories of causation, as investigated in swine, are three in number.

1. *Bacterial.*—Jaegar cultivated what he believed to be a specific organism, *Bacillus coli lymphaticum aerogenes*, which entered the submucous lymphatics through a chronically inflamed mucous membrane.

2. *Hæmatogenous.*—John Hunter suggested that the gas escaped from the blood, either from natural causes or through diseased blood-vessels.

3. *Mechanical.*—The gas being forced into the intestinal wall through an abrasion in the mucosa.

The absence of signs of inflammation, the fact that there are no adhesions nor lymph, and also that no specific organism has been cultivated in man, all tend to disprove an infective origin. The majority are due to mechanical causes. Air enters through an abrasion in the mucous membrane and so gains the lymphatic network, and is driven along by constant pressure and by peristalsis. The irritation of the gas leads to an obliterating endolymphangitis, and so cysts are formed. The constant pressure and high tension of the air are maintained by the vomiting and flatulence of the associated lesion (ulcer).

The cysts are best left alone, as they tend to disappear spontaneously. Crushing or puncture is dangerous, as the bowel may perforate from the resulting weakness.

On Sept. 5th, 1927, a sparsely built man, aged 40, was admitted to the North Staffordshire Royal Infirmary with the following history.

He had complained of "indigestion" for years. This took the nature of pain in the epigastrium immediately after food, followed by vomiting, which relieved the pain. There was no hæmatemesis. The usual remissions were present; the appetite was fair, and he was not losing weight. He suffered from constipation. At 6.30 A.M. that day he was getting dressed, when he had a sudden pain in the epigastrium. He vomited and collapsed, and was brought to hospital.

Examination revealed obvious signs of a perforated gastric ulcer. He was operated upon by Mr. Reginald Alcock. On opening the abdomen much slightly turbid fluid was found. There was a perforation on the anterior surface of the stomach about 1 inch from the pylorus. This was surrounded by a large area of induration, rendering oversewing of the ulcer difficult. Further examination showed a curious condition in a loop of small intestine. For about 9 inches the gut seemed to be replaced by vesicles containing air or gas. Some of these were punctured, but no fluid escaped. A little further on were two small buds of the same cystic nature, about the size of a cherry. Excision of the loop was inadvisable, on account of the serious condition of the patient. A lateral anastomosis was performed and the abdomen closed with drainage in the usual way.

The patient was expected to perforate at the site of the vesicles and die, but he made an uninterrupted recovery, and left the hospital seemingly fit. He returned, however, complaining of incessant pain and vomiting, so was readmitted for a gastro-jejunostomy.

On Nov. 29th, 1927, he was again operated upon by Mr. Alcock. The induration causing pyloric obstruction was still present, so a post-gastrojejunostomy was performed, and the appendix was removed. The site of the lateral anastomosis was slightly adherent, but there was no trace whatsoever of the vesicular condition, the bowel being roughened and cicatrised. The patient is still in hospital, and is progressing very satisfactorily.

I am indebted to Mr. Alcock for permission to publish this case.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

COMBINED SECTIONS OF LARYNGOLOGY, MEDICINE, AND ODONTOLOGY.

INFLUENCE OF NASO-ORAL SEPSIS ON THE LUNGS AND GASTRO-INTESTINAL TRACT.

THESE combined Sections met on Jan. 11th to discuss the above subject, Mr. HAROLD BARWELL (President of the first-named) being in the chair.

The Laryngologist's Point of View.

Mr. E. D. DAVIS said that laryngologists were still somewhat backward in calling in the aid of the physician, and he hoped that the discussion would encourage them to regard the patient's condition as a whole as well as the region of their own specialty. Nasal sepsis could influence the lungs and lower respiratory tract (1) by direct extension of inflammation to the larynx, trachea, and bronchi, or by the blood and lymph streams; or (2) by aggravating or increasing existing pulmonary lesions; or (3) the nasal sepsis might be part of the general infection involving the upper and lower respiratory tract. Direct infection to pharynx, larynx, and trachea was seen in the common cold. A pneumococcal infection of the nose and nasal sinuses might precede or accompany pneumonia. A. R. Felty and C. A. Heatley, investigating the causal organism of lobar pneumonia in 16 cases, showed that pneumococci of corresponding type occurred also in the patients' nose; and in five were also found in the blood. Where there was profuse suppuration in the nasal sinuses the pus streamed down from under the soft palate and collected in the lower pharynx below, behind the arytenoid cartilages, and in the pyriform fossæ. This pus was always swallowed, and he had never seen it in the larynx or trachea, though he had frequently searched for it; its entry was prevented by the ciliated epithelium and by the cough-reflex. The cleansing power of the trachea was enormous, and experimental attempts to produce pneumonia by introducing cultures into the naso-pharynx failed unless large doses of a high virulence were used. Still, a direct spread of the inflammation to the larynx and trachea often accompanied nasal suppuration, and was helped by the coughing and hawking. Investigations in America showed that infection could extend by the lymphatics to the chest. When an inflammatory condition of lungs already existed it was certainly aggravated by nasal sepsis, and tuberculous patients had no resistance to pyogenic and catarrhal infections. Suppuration in the sinuses sometimes followed bronchiectasis and bronchitis.

Looking through the notes of 100 of his cases of nasal sinus suppuration, Mr. Davis found that in 9 the infection was confined to the nose, whilst there were four patients with bronchitis, one with bronchiectasis, two with asthma, one with abscess of the lung, one with colitis, and one with duodenal ulcer. It was likely, however, that some of the 90 patients would later have secondary pulmonary infections. Of 474 cases of definite pulmonary tuberculosis which

he had investigated at Mount Vernon Hospital, only five showed nasal sinus suppuration, but there were 11 with atrophic rhinitis and five with nasal polypi without suppuration. It was difficult to prove that chronic suppuration in the sinuses was a cause of bronchiectasis; but Dennis reported 24 cases of bronchiectasis in which the condition was present, being improved in 16 by treatment of the nose. In his own experience gastro-intestinal infection arising from the nose was rare. Septic teeth, he thought, were more likely to affect the gastro-intestinal tract than was nasal sepsis. A case of chronic suppuration of the nasal sinuses should be regarded as a potential pulmonary case, and general as well as local treatment should be started.

Mr. C. A. S. RIDOUT said that children were often sent to his clinic from the municipal tuberculosis clinic, who had general debility with bronchial signs, such as crepitations, possibly with night sweating and enlargement of cervical glands, but in whom no tubercle bacilli had been found. All these patients had enlarged and infected tonsils and adenoids, generally they had marked dental caries, and some had infection of the antra of Highmore. With attention to the local seats of sepsis the chest condition usually cleared up. These cases showed the importance of every tuberculosis clinic being in a position to consult with a laryngologist and otologist. The relationship of gastric ulcer to nasal and oral sepsis also required more team-work between the surgeon, physician, laryngologist, and dental surgeon than had been usual. He had done a considerable amount of general surgery, and had constantly noticed that oral sepsis was associated with such conditions as gastric ulcer and carcinoma. Probably there was in the stomach an early stage, before an ulcer formed, at which the aid of the laryngologist might well be all-important.

The Medical Point of View.

Dr. R. A. YOUNG began by paying a warm tribute to the pioneer work of Dr. William Hunter on dental and oral sepsis. It was difficult, he said, to find a satisfying definition of sepsis, but, for the purposes of this discussion, it could be taken to mean the conditions produced by local infections with pyogenic organisms. Hence the chief conditions to be discussed were those of streptococcal origin, and in these infections bony structures were very apt to be involved. There were at least six ways in which local sepsis of mouth, nose, and pharynx might affect the respiratory mechanism: (1) By direct spread along the mucous or submucous tissues. (2) Mechanically, by the nasal obstruction preventing the filtering and warming functions of the nose, and thus leading to catarrh of air passages and alveoli. (3) By the inhalation of septic organisms derived from the nose or mouth, leading to infective conditions of the bronchi or lungs, or by particulate inhalation, especially when there was widespread ulcerative disease, or when the patient was unconscious, as during anæsthesia. For all operations there should be the strictest hygiene of the mouth. (4) Indirectly, by toxic absorption influencing the blood and immunity of the patient, such an influence being apparent wherever there was long-continued sepsis. Sometimes there were also indications of endocrine exhaustion, as shown by lowered blood pressure and appearances of mild hypothyroidism in patients with advanced oral sepsis. (5) By septicæmia or infective endocarditis originating from oro-nasal sepsis. Lastly, there might be (6) a painful fibrositis of the muscles of the thoracic cage, leading to pleurodynia. Dr. Young concluded by considering the chief clinical results of these processes, including laryngitis, bronchiectasis, pneumonia, gangrene of lung, and tuberculosis, and said that if the discussion impressed on those concerned with treating respiratory diseases the necessity for attending to abnormal conditions of the mouth and nose, it would have served a useful purpose.

Dr. IZOD BENNETT said that conclusive proof of the dependence of gastro-intestinal disease on sepsis higher in the alimentary canal was not yet forthcoming. Much of the evidence now available, however, pointed so clearly in one direction that even now some dogmatism was justified. There were two paths by which bacteria or their toxins could affect the stomach and lower intestinal tract: (1) by the swallowing of bacteria and pus, and (2) by direct passage into the blood stream of pathogenic organisms arising in the teeth, tonsils, naso-pharynx, or sinuses, with consequent appearance of embolic phenomena in other parts. He did not regard the swallowing of bacteria and pus from the teeth, nose, and mouth as so frequent a cause of gastric and intestinal disease as was formerly supposed. It must be remembered that many organisms were habitually ingested with food. Danger seemed specially to be present when the swallowing of pus was coincident with achylia. With regard to the second path of pus, many thought that infection via the blood stream was the commonest cause of gastric and duodenal ulcer. In 1922 Dr. Newton Pitt had shown that despite surgical and medical advances, the number of fatal cases of peritonitis following perforation of gastric and duodenal ulcer rose from nil in the five years, 1880–84, to 111 in 1915–19. Was this related to an increasing prevalence of sepsis in the mouth and throat? He believed that in all sections of society it was an everyday occurrence for dental surgeons to take measures for the preservation of teeth, whose pulp was infected, instead of extracting them, as was the former practice. Could such teeth be regarded as subsequently free from all sepsis? He considered that the filling of devitalised and artificially anæsthetised teeth was contrary to the accepted principles of the surgery of bone disease. The practice might bear a relationship to the increase of gastric and duodenal ulcer, cholecystitis, and appendicitis.

The Dentist's Point of View.

Mr. J. G. TURNER said that the evil influence of naso-oral sepsis was beyond doubt. He quoted four striking cases of gastric and intestinal trouble of marked degree which were cured by removal of all offending teeth. The smell of most mouths was due to stagnating material, chiefly food made from finely-ground flour, among the teeth, which had been made putrid by bacteria. Sticky food would only lodge where a resting-place had been provided or prepared for it. He agreed with Dr. Bennett's suggestion that ill-executed dental work and over-conservatism in respect of dead teeth were responsible for a large amount of illness. Pus and putrid material might inhibit the secretion of gastric juice. Some patients vomited septic material which had remained unaltered during its residence in the stomach. Could a man, he asked, immunise himself against his own dental sepsis? In the mouth the clinical answer was in the negative.

Mr. A. BULLEID said it was difficult to be certain that the bacteriological findings in cultures revealed the causal organisms of the disease under investigation, because the organisms isolated did not differ markedly from those in the healthy mouth. Agglutination was the most satisfactory of serological reactions. Infections of the nares and naso-pharynx were more easily investigated, as in health the secretions were normally sterile. All chronic pulmonary infection was benefited by eradication of naso-oral sepsis. Bacteriological examination of the sputum and of material from naso-oral foci should always be carried out when such infection was present, as prophylactic vaccination subsequent to the medical treatment of the lung condition was of great importance. He discussed the significance of the *Leptothrix buccalis* group of organisms in relation to the formation of tartar on the teeth.

Discussion.

Dr. F. A. PICKWORTH (Birmingham) sent a contribution, which was presented by Mr. Davis. It related a case of diplococcal infection of the sphenoidal sinus, with associated hæmorrhages in the stomach. The patient was a man, aged 62, who was

insane, and had a five years' history of epilepsy. The Wassermann reaction was negative. The bony walls of the sphenoidal sinus were remarkably thick, and the membranes of the sinus on both sides showed hypertrophy. The gastric mucosa showed regular surface hæmorrhages. Microscopically the sinus epithelium was invaded by numerous cocci. Even in the gastric epithelium there were cocci of similar character to those in the sphenoidal sinus. In addition the organisms were found in the pituitary capsule and gland.

Dr. P. WATSON-WILLIAMS (Bristol) spoke of the value of the work being carried on at Birmingham University by Dr. T. C. Graves and Dr. Pickworth, especially in the subject under discussion. In 1921 he, Dr. Watson-Williams, published a paper calling attention to the frequency of appendicitis owning, apparently, nasal sepsis as its cause. These were cases of great chronicity, and it was chiefly in latent cases, in which but little pus was evident, that systemic manifestations were found; they were apt to be overlooked unless carefully searched for. He quoted a number of typical cases. He pointed out that the greatly increased frequency of gastric, duodenal, and appendicular troubles since 1889 synchronised with the epidemicity of influenza.

Dr. E. STOLKIND said that even when the teeth had been removed it did not always follow that the secondary disease cleared up. Among many patients with digestive and pulmonary disease, very few reported improvement after extraction of their teeth, and he considered that the close relationship between disease of teeth and lungs and gastro-intestinal tract had not yet been proved.

Sir JAMES DUNDAS-GRANT spoke of the frequency with which it was found that cases with pulmonary tuberculosis at Brompton Hospital improved unexpectedly when the nose was washed out with a prescribed lotion. Sometimes suppurative disease of the naso-pharynx produced a form of laryngitis very difficult to distinguish from tuberculosis. He had seen the vocal cords coated with a greenish crust of pus which had obviously found its way there from an infected sinus. Washing out of the nose greatly improved the throat condition. He felt sure that occasionally bronchiectasis was caused by sinusitis.

Dr. T. A. CLARKE said he felt convinced that oral and nasal sepsis was a frequent cause of spasmodic dysphagia. In nearly all the 200 cases of carcinoma of the œsophagus which he had investigated dental sepsis was present, in many advanced. Even in these cases attention to the sepsis temporarily improved the swallowing.

Mr. A. F. MACCALLAN spoke of ocular indications that general resistance of the body was giving way because of the action of chronic sepsis, chiefly in teeth, tonsils, or colon. Since last May he had seen 74 in which indications of this kind were present. Although 90 per cent. of them had 6/6 vision, there were conditions such as blepharitis, and the slit-lamp revealed slight opacities in the periphery of the lens and in the vitreous, seen when the pupil was dilated, and also hyperæmia of the macula. He advocated a more frequent ophthalmic examination of patients to ascertain their resistance and how far the disease had progressed.

Dr. W. HILL did not think that pulmonary, gastric, and intestinal disease often resulted from focal disease in the nose, though he granted that a relationship had sometimes been clearly established in frankly suppurative cases. Fœtor of itself was not necessarily an indication of the presence of pathogenic micro-organisms.

Mr. CYRIL HORSFORD declared that in his own experience there were a large number of cases of gastro-intestinal disease which were directly due to infection of the nose and throat. Treatment of infections of antra or sinuses sometimes cleared up the gastric condition when the usual treatment proved unavailing.

RECEPTION AT THE ROYAL SOCIETY OF MEDICINE.

SAINTS, MEDICINE, AND SURGERY.

A LARGE company of Fellows and guests attended the reception at the Royal Society of Medicine on Jan. 16th, when Dr. JANE WALKER delivered an address on medical saints. It had been a real difficulty, she said, to choose a title which would exclude those very many medical men and women who had been so full of grace and holiness as to merit the term "saint." She proposed to limit herself to those Christian Saints who had been concerned in the medical and surgical details of the profession of healing and, indeed, to the best known and most important among them, for their total number was very great. Of some, for instance St. Conrad, patron of sufferers from hernia and rupture, she had been unable to find any pictures. Saints, she pointed out, were represented by the old masters as patrons of individuals or of cities, but as time went on there was a tendency for the donor of the painting to increase in size and sanctity at the expense of the saint. In the van der Goes "St. Victor," shown at the Glasgow Gallery, the donor was quite as large as the saint and dressed in monkish garb. A good example of a saint as patron of a city was found in the Mantegna St. George, patron saint of Venice, as well as of England. Saints were also depicted, however, in their rôle of protectors against, and supporters of sufferers from, disease. Of these the first was St. Luke. Modern criticism tended to deny to the third evangelist any medical status, but Dr. Walker pointed out that it was very like a doctor to omit, in describing the incident of the woman who had had an issue of blood, the remark, supplied by Matthew and Mark, that she had spent all her living on physicians and was no better but rather worse. It has been suggested that St. Thomas, who was an honest sceptic, though a reverent one, would be a better patron saint for doctors than St. Luke. In Dr. Walker's opinion the third gospel showed many signs of medical knowledge, for instance, the reference to Peter's wife's mother when she was holden with a "great fever," a recognised diagnosis in those days. St. Luke was the patron saint of artists, and himself a painter. It was while sitting to him for a portrait that the Virgin was supposed to have told him all those intimate details of the early life of her Son which are found in no other narrative. A picture by Dieric Bouts, on view at the Academy last year, showed St. Luke painting this portrait. Next in importance to St. Luke was St. Pantaleone. He was said to have been very beautiful and of graceful manners, and a high favourite with the emperor. He had been tied to an olive tree and beheaded, and an olive had sprung up where the head fell, so that he was generally represented wearing the long robes of a physician and holding an olive branch. St. Cosmas and St. Damian would be the subject of another lecture to the society later on, but Dr. Walker could not resist showing the picture representing St. Damian's one lapse from grace in the matter of fees. An importunate widow presses on him a money-bag which he sternly rejects with the right hand whilst receiving it into his left. "Characteristic attitude of a physician refusing a fee" observed the lecturer as the reproduction was thrown on the screen. St. Cosmas had been so incensed with his twin for this sin that he had declared that they should not be buried in the same grave. The story ran, however, that when the second grave was being prepared, a camel had arrived, with tears streaming from its eyes, and announced that it represented all the animals who had been healed by these good men. It had begged that they should not be separated in death. In showing the well-known picture of the graft of a dead Moor's leg on to the amputation stump of a man with a cancer of the shin, Dr. Walker drew attention to the scars of the cautery on the head of an onlooker, to the "septic dog" in the foreground, and to the stupefied expression of the patient. Narcotics were seldom

mentioned, she said, because they were so very common in those days.

Three Virgin Martyrs.

St. Margaret was the patron saint of pregnancy because she had come out of the mouth of the dragon, from all time an emblem of danger. She was often represented with the dragon at her feet, still clasping in his jaws a portion of her robe. A beautiful van Eyck in the National Gallery represented a husband presenting his wife to his family. That she was intended to be pregnant and that her pose was not merely the fashionable one of the time was proved by the presence of the little statue of St. Margaret on the bedpost. An interesting painting was the "Nativity" of Petrus Christus, where St. Joseph was shown with a candle ushering in a midwife—too late to do aught but adore. This feature, Dr. Walker believed, never appeared in southern works of art. St. Catherine, of Alexandria, had been a great orator and was patron saint of the tongue and of learning. She was represented, teaching, in a picture by Goosen van der Weyden, and, since she had been a princess, she was always shown wearing a crown. Her father had considered her too wonderful for any human mate, and hence had arisen the legend of the mystic marriage, represented by many painters, for instance Bernadino Luigi. She had been tortured on four wheels revolving in different directions, but the wheels had been miraculously smashed and she had therefore been beheaded. Her body had been carried by angels to Mount Sinai. St. Barbara was the patron saint of sufferers from accidents and explosions. Her father, also, had considered her too beautiful for mortal eyes to look upon and had therefore imprisoned her in a tall tower, which became her emblem. She had asked for three windows instead of the two he had planned, remarking that light came to the soul through three windows. He had thence concluded that she must be a Christian and had attended to her tortures himself, finally cutting off her head. Among the painters of Barbara and her tower had been van Eyck and Holbein.

Plague and Pestilence.

St. Sebastian, born in Gaul in 288, had been a member of the Pretorian Guard and a favourite of the emperor, who had vainly urged him to deny his faith. The arrows were always shown sticking into non-vital spots, and he had, in fact, recovered from them to die from beating with clubs. Occasionally a picture mistakenly showed an arrow in a vital spot, as did the one in the Uffizi Galleries, Florence. The arrow had been the emblem of plague from olden time, as suggested by the text "the arrow that flieth by noonday." St. Roc, born in Montpellier with a small red cross on his breast, had made a pilgrimage to Rome in the course of which he had encountered plague and discovered his success in treating the sufferers. He earnestly hoped, said Dr. Walker, that he would get the disease himself, and in the end succeeded in acquiring the ulcer of the leg which his many portraits represent. The pain was so great that he cried out, and was turned out of the city and would have died in the forest had not his little dog daily fetched him a loaf. When he returned to his native city he was so thin and worn that nobody recognised him, and he was put to death as a spy. He left a document, however, revealing his identity and his significance for plague-stricken communities. Venice, being much subject to plague, decided that she could best do with his body, and therefore stole it and founded the well-known church and convent.

The Eye, Breast, Teeth, Stomach, Throat, and Lungs.

There were confused and obscure stories about St. Lucy, patron of the eyes and of the labouring poor. The later ones said that her lover had inordinately admired her eyes, and that therefore she had plucked them out and sent them to him. He had immediately become a Christian and her sight had been miraculously restored. In the end she had died through having her neck pierced by a sword. She was frequently represented with two eyes on a sort of skewer in her hand, as in the Bergamo in Rome. St. Agatha had been cast into a house of ill-fame, but as she had refused to live a life of infamy her breasts had been cut off. Painters varied in the amount they left to the imagination, but she generally bore her breasts on a plate in her hand. St. Apollonia had been commanded to worship a statue, but had instead exorcised the devil from it, so that the statue had fallen to pieces. The governor, enraged, had had all her teeth pulled out, one by one, and later she had been burned to death. Patron of sufferers from stomach-ache and allied disorders, St. Erasmus had been tortured by having his entrails wound off on a sort of winch. He was usually depicted with his bishop's mitre and a kind of spindle in his hand, representing his intestines. St. Blaise, patron of diseases of the throat and of woolcombers and wild animals, had been a Greek bishop in the time of Diocletian and had cured a child who was being choked by a fish-bone. He had been scraped to death with large iron combs, very like the implements of the modern woolcomber. St. Ansano had been baptised at the age of 12 and had escaped from the persecution of Diocletian to Siena, where, however, the proconsul had seized him and, having failed to burn him, had cut off his head. Pictures showed him holding his lungs and liver in his hands, and he had become, for no known reason, patron of consumptives. St. Catherine of Siena, born in 1380, had desired the religious life from her infancy, but her father had only given his consent after finding her praying with a dove on her head. She had tended the sick, but had died at an early age and cramped her usefulness by excessive privation. She had been a woman of great strength of mind and body, and had been responsible for sending the Pope back to Rome from Avignon. She was portrayed wearing the habit of the Dominicans and holding a lily.

The vote of thanks to Dr. Walker, proposed by Dr. Percy Smith, included also the Wellcome Historical Medical Museum and Miss Marie Leon, who had lent many of the exhibits which were thrown on the screen and put on view in the library.

SOCIETY OF BRITISH NEUROLOGICAL SURGEONS.

THE third meeting of this Society was held in London in December last. Sir Charles Ballance, retiring from the Presidency, was made Hon. President, and Mr. Wilfred Trotter was elected President. It was announced that Dr. W. W. Keen (Philadelphia) had been made an Emeritus Member and Prof. Harvey Cushing (Boston) and Dr. C. H. Frazier (Philadelphia) Honorary Members.

Mr. H. S. Souttar operated at the London Hospital, using his craniotome, and cut a large frontal flap under local anæsthesia in an exploration for a para-sagittal cerebral tumour. He afterwards demonstrated cases and apparatus. The later proceedings took place at the Institute of Anatomy, University College. Prof. Elliot Smith reviewed some of the commonly neglected points in intracranial anatomy of interest to the neurological surgeon, referring to the work of Dr. Harris on the development of the diploe, to the course of the abducens nerve, and to his own work on the visual area and the relations of the carotid arteries to the optic chiasma. Papers were then read by Mr. L. R. Broster on a Case of Suprarenal Virility with Operative Findings, by Mr. H. W. B. Cairns on the Effect of Trauma in Disclosing New Clinical Signs in Neurological Cases, and by Mr. Julian Taylor on the Nature of Bone Invasion and Proliferation in Cases of Meningeal Tumour. A discussion on the Surgery of Head Injuries followed. It brought to light a very general conservatism with respect to early operation except in cases where a localised hæmorrhage could be diagnosed, and (of course) in cases of penetrating wounds.

The following morning was devoted to the display of patients by London members, and to a demonstration by Dr. H. A. Harris, of preparations in the Museum of the Institute of Anatomy, University College.

HUNTERIAN SOCIETY.

ON Monday last, Jan. 16th, this Society met in the Mansion House, with Mr. A. MORTIMER WOOLF, the President, in the chair, to hear Dr. HOWARD KELLY, of Baltimore, deliver the Hunterian oration for the year. Dr. Howard Kelly reviewed in his paper the whole history of surgery, taking as his text the Hippocratic maxim τριβὴ μετὰ λόγου, which he wittily translated

"GRUBBING WITH REASONING."

These three words had been, he said, the guiding principle of surgery and her sister medicine all through the ages. In the pursuance of this ideal surgery had grown apace; in its neglect she had lost her vision and become for a time dishonoured. He was indebted to Sir Clifford Allbutt, who, quoting these three master-words in 1904, had completely transformed his outlook on the history of surgery. Whereas he had been used to view the development of surgery as a slow, blind, evolutionary accretion, governed only by the one critical standard of a knowledge of anatomy, he now saw its history perfused with a new light and an abiding interest, and the whole of its past ruled by one glorious principle. This great maxim, "rubbing with reasoning," had been indispensable to progress of all kinds throughout all the ages. Τριβή was the rub and wear of daily contact with facts; "grubbing" expressed its essential meaning even better than "rubbing." Λόγος was the idea, man's supreme gift of cogent reason. Τριβή was the phenomenon, λόγος the noumenon ever shimmering behind the phenomenon in all Nature. When τριβή ruled λόγος, the light went out and men groped in the darkness of materialism; did λόγος lord it over τριβή, superstition and vagaries entered, bringing disorganisation. When, however, the two were wedded by the conjunctive μετά, their progeny was true science. This trilogy had been imparted to mankind by our remotest ancestor, to govern surgeons in all their ways at the birth of their craft. Applied to the history of the 70 generations from Hippocrates to Hunter it became a talisman revealing progress and uncovering the ways of error.

The Adolescence of Surgery.

The stream of medical knowledge had its source in a man who was perhaps the greatest physician of all past time, and who established medicine on a broad scientific basis with high ethical ideals.

Hippocrates' treatise on fractures and dislocations, joints, and chronic ailments was comparable with recent work, and his care of the wound left little to be desired before the era of Lister. He anticipated healing by first intention in fresh wounds, boiled the water used for washing, and ordered the cleanliness of the operator's hands and nails. Treatment had at first been largely hygienic and empirical; the Greeks, as Garrison noted, used not so much to cure as to prognosticate. Modern surgery owed to the Coan sage the example of the open mind, the alert, cultivated use of the faculties, and the habit of utilising experience.

Hippocrates had bequeathed his Aladdin's lamp of personal experience and judgments to be rubbed by generation after generation, but with it he had unfortunately handed down a λόγος, in the shape of the inherited humoral doctrine, which had escaped the discipline of τριβή. Surgery had therefore advanced slowly for the next 500 years, although it had received material aid from the Alexandrian school, whose anatomy had been summarised by Celsus in his "De Re Medicinâ."

The next great landmark was Galen, the speculative philosopher, the peripatetic physician. Galen had resembled John Hunter in the catholicity of his interests, but had left "no good accounts of clinical cases, only miraculous cures" by polypharmacy. He had approved the Hippocratic words of wisdom, but had unfortunately lacked Hippocrates' modesty, and so had lost the talisman and held captive, by his autoschediastic lucubrations, a school of blind Galenists for over a thousand years. His dogmatism had produced a millennium of darkness that could be felt, and his fatal doctrine had been that a cart goes best if the horse is set to pushing it from behind—i.e., that theory should precede and control practice, and that τριβή should be wholly subordinate to λόγος. The mischief he had done was most evident in the treatment accorded to Copernicus, Brahe, Kepler, and Galileo in the sixteenth and seventeenth centuries, and in the astrology, alchemy, and demonology that flourished to the exclusion of surgery, which, relegated to the barbers, became literally barbarous.

Mediæval Struggles.

Towards the end of the twelfth century light had begun to return with a little group of humble men, "reared in base apprenticeships, not only illiterate but forbidden even the means of learning," who by τριβή μετὰ λόγου had zealously sought the truth and proclaimed it, sometimes in the despised vernacular. Roger (1180) had done many things besides suturing intestines over a hollow tube and using ligatures in hæmorrhage. Salicetus (1201–1277) had substituted the knife for the fiendish but widely used Arabian cautery; had divided nerves, and kept good case-histories. Lanfranc, his pupil, had become the titular head of French surgery. Theodore of Lucca (1206–1277) had been a zealous apostle of union by first intention, insisting "It is not necessary that pus should be generated in wounds." Henry de Mondeville (1260–1320) had been a vigorous opponent of tradition and had declared with vehemence that "God did not exhaust his creative power in making Galen." Henry had been "the last champion in his day of two causes: the solidarity of medicine and union by first intention—the second lost for 600 years." Mediæval surgery had ended with Guy de Chauliac (1300–1370) a virile, inquisitive spirit who had cast out the lingering "sorcery, jugglery, astrology, and mysticism," and whose "Chirurgia Magna" was a masterpiece of learned luminous writing. In opposition to Henry and Theodoric, he had held that the surgeon should actively insist that the wound proceed in the approved fashion through its numerous stages, from "coction" to complete cicatrisation.

Ambroise Paré.

Paré's name had stood deservedly pre-eminent in the records of the last 350 years, but the reason for this pre-eminence was not at first sight easy to understand. He had been a barber's apprentice of no scholarship, snubbed by his compeers and writing in the vernacular, but by sheer merit he had cast all his predecessors into the shade and towered above his ridiculous influential contemporaries. The cause lay not in his ligating of arteries, but in his innate greatness and nobility of character. Men had known him but to love, honour, and respect him, and so the indefinable aroma of his reputation, commingled with his great works, was as potent to-day as it had been 400 years ago. An indefatigable worker, he had been fortunate in having a vast war experience. His predecessors had exhumed surgery and set her on her feet; Paré had rehabilitated her and presented her at court and to the world. No surgeon had ever made a more effective conjunctive use of τριβή and λόγος, multiple experiences digested and coördinated by reasoning.

Between Paré and Hunter there had been few surgeon torch-bearers. After Richard Wiseman (1622–1676) there had appeared William Cheselden (1688–1752), and Percival Pott (1714–1788), the former the patron saint of lithotomists and the latter an original genius and writer of masterpieces; these had been John Hunter's teachers and worthy of their great pupil. Although there was a tendency to pass over this pre-Hunterian age as sterile, much had occurred in it that was of first-rate scientific importance. Anatomy had made notable advances during this interval, despite the lack of material (Dr. Howard

Kelly here interposed some entertaining stories of "body-snatchers"), but its three leading events had been Harvey's discovery of the circulation of the blood (1628), the opening-up of histology and physiology by Malphighi (1626–1694), and the foundation of modern pathological anatomy which was laid by Morgagni (1682–1771) in his eightieth year; not to mention Bonet's "Sepulcretum" (1679), a "pathological library" containing all the prime needs of the surgeon.

John Hunter, and After.

Genius, for effective expression, needed a favourable environment, and there had never been an age which teemed so richly with scientific promise as that into which Hunter had been born. Chemistry had been growing under the hands of Scheele, Black, Priestley, Lavoisier, and later Humphry Davy, whose mantle had fallen on Faraday. Geology was being moulded into a veritable science by such men as James Hutton, William Smith, and James Playfair. Hunter's own collection of fossils, bequeathed to Sir Richard Owen, were basic in English geology. In botany, mycology, astronomy, economy, mechanics, art, morals, and religion new life was also stirring. Thus the thrill of birth had been in the air, and surgery, though the Benjamin of the sciences, had proved no laggard.

The twin novæ, William and John Hunter, had been born in 1718 and 1728 respectively, and had each lived 65 years. John had spent his boyhood roaming abroad in the open, undisciplined by his parents and neglecting letters for Nature, which, however, had nursed him and taught him never-to-be-forgotten lore. At 20 he had been undecided whether to be a soldier or a surgeon, but his brother's established reputation had turned the scale. Three years' "grubbing" had made him, with his natural talent, a highly skilled anatomist and a qualified surgeon, and he had then entered upon a period of great fruitfulness—not as a soaring genius but as a true exponent of τριβή, or of his own maxim, "Don't think; try." The regeneration of the ancient art of surgery had dawned in the enthronement of the basic principles of hard work with fruitful hands and clarified vision, observation, and record. What would we not give, asked the speaker, for an ergograph of one of John's days? He had subjected himself to an exemplary and rigorous routine in the exploration of fields some of which were closely allied to surgery and some of which were not, and had pressed his labours to the end of his days, in spite of the Damoclean sword of an agonising and ultimately fatal angina. As well as becoming a great surgeon he had also made himself a master of zoology and geology, and the new art of taxonomy, based as it was on physiology, had interested him greatly.

Dr. Howard Kelly then reviewed the many important contributions of John Hunter to anatomy, pathology, surgery, and the allied sciences. His one deficiency had been that he was no encyclopædist of the work of others; he had failed to realise, like many before and after him, that a wide distribution of knowledge over many workers was likely in the end to accomplish more even than one great mind. The great century had therefore reached a fitting climax in the career of a man who had done more than any other to erect for surgery—that most beneficent of all human activities—the two imperishable pillars upon which, in common with all other science, it rested; the τριβή of skilful painstaking observation and accumulation of data, and the λόγος of highly trained reasoning, analysis, classification, and the coördination and abstraction of laws.

In the time of Hunter, however, surgery as it existed to-day had lain profoundly concealed in the womb of the future. In the absence of a new and transforming impulse an acme had probably been reached similar to that proclaimed by Michaelis, of Kiel, when, last century, he had performed on Frau Adametz her fourth Cæsarean section. That impulse, however, had been given, first by the pioneers of anæsthesia and cellular pathology, and most decisively of all by the hero who, working on the basic principles of John Hunter, had converted the reeking hospitals of his time into temples of health, sweetness, comfort, and happy associations; who had, in spite of opposition, ridicule, and obloquy, brought down heaven's greatest physical blessing and destroyed our direst enemies, the germs of wound infection. Such a man deserved, even more than the speaker's great countryman, Franklin, the encomium "Fulmen que eripuit cœlo, sceptrumque tyrannis." "Gentlemen," concluded Dr. Howard Kelly, "let us ever hold in highest honour the names of John Hunter and Joseph Lister."

In replying to a vote of thanks proposed by Mr. T. H. OPENSHAW and seconded by Dr. H. A. ELLIS, Dr. HOWARD KELLY presented to the Society an autograph letter of John Hunter for addition to their collection.

Reviews and Notices of Books.

EMERGENCIES OF A GENERAL PRACTICE.

Second edition. By the late NATHAN CLARK MORSE, A.B., M.D., F.A.C.S. Revised and rewritten by AMOS WATSON COLCORD, M.D., Surgeon, Carnegie Steel Co.; Surgeon, Pennsylvania Railroad System. London: Henry Kimpton. 1927. Pp. 514. 42*s*.

THIS book is prepared with a view to assisting those general practitioners who are not in a position to send cases to a specialist, to deal with their emergencies as specialists would; it should make a special appeal to the doctor resident in rural communities and small towns or in the colonies. Originally written by Dr. Morse, it has been revised for its second edition by Dr. Colcord, who pays a glowing tribute to the original author.

After a short chapter on instruments and solutions required in surgical emergencies, there follows a useful chapter on the removal of foreign bodies from all parts of the body where they may lodge; the value of this section as a quick and handy source of reference need not be elaborated. A chapter on first-aid suggests requisites in first-aid boxes, and deals with the subject from the points of view of laymen, nurses, and physicians. Treatment of the drowning is fully described. An excellent section on carbon monoxide poisoning follows, in which it is laid down that CO is not a cell-poison but kills merely by deprivation of oxygen—a most important factor underlying the treatment. This section is particularly well illustrated.

Two chapters on surgical emergencies deal with Carrel-Dakin methods of wound-treatment, Dr. A. B. Kanavel's methods of treatment of infected hands and fingers, abdominal emergencies (described at some length), scalp wounds, and injuries to the eyes. Why icterus is included among surgical emergencies is not clear, especially as the operation of cholecystoduodenostomy is not mentioned.

The discussion of certain medical emergencies is less satisfactorily dealt with; the treatment of hæmoptysis is too dogmatic, being based neither upon physiological nor statistical considerations; powdered alum, for instance, is recommended, and the nitrites are described as useless without further ado. Hæmatemesis is described as "frequently following severe injuries over the epigastrium"; most of the remedies suggested are given by the mouth, the advisability of keeping the stomach completely empty not being mentioned. The use of insulin in diabetic coma is discussed in five lines. There follows more useful sections on food-poisoning, burns, rabies, tetanus, and retention of urine.

Fractures receive 100 pages jointly with dislocations; this section is well illustrated; the methods recommended are evidently those of which the author has experience, and are mostly orthodox ones. A chapter on emergency amputations follows. The section on obstetric emergencies includes Cæsarean section, the use of forceps, and placenta prævia. In

each of these conditions the author gives us the principles which have guided him in a busy practice. Finally a 70-page section on poisoning from all kinds of sources completes the book; it includes many poisons not found in more compact handbooks, and should be useful for reference.

The book will not fail to interest those medical men who have to tackle their own emergencies. It represents the accumulated experience of at least two busy and varied lives, and contains many a useful hint that does not appear in more academic works.

ENZYMES.

Lehrbuch der Enzyme. Chemie, Physikalische Chemie und Biologie. By Prof. CARL OPPENHEIMER, Dr. phil. et med., in Berlin. Leipzig: Georg Thieme. 1927. Pp. 660.

THIS work aims at covering the whole ground of enzyme action from the point of view of a summary. The book, which is divided into two parts, starts with an account of the chemistry of enzyme action followed by an interesting chapter on the chemical nature of enzymes. An excellent summary of the recent work of Prof. Rich. Willstätter (Munich) is included, and might with advantage be expanded in a subsequent edition. The third chapter deals with factors influencing enzyme action in general. On p. 51 a useful table gives the optimum pH for the action of a very wide series of enzymes, the authority being quoted in each case. The action of neutral salts, various ions, and organic substances is discussed, and the antigenic properties of enzymes are also considered. The next chapter is devoted to the purely physical, chemical, and kinetic aspects of enzyme action, and is written in conjunction with Dr. Richard Kuhn. One of the most interesting parts of this section is the description of the methods of determining the isoelectric point of the various enzymes, which is omitted in most books. The section concludes with a brief account of the absorption phenomena in relation to enzymes. The final chapter of the first half of the book is concerned with the distribution and preparation of enzymes. This is dealt with in a general manner and includes an interesting section on the probable method of secretion of these bodies.

The second part of the book is divided into 16 chapters consisting of a summary of all the recent work upon special enzymes. Each chapter is devoted either to one enzyme, or to a group of similar enzymes. The summaries have been admirably made, few researches of any note having been omitted, and probably for this reason very few references are to be found, but a full bibliography would have been invaluable, and we hope it may be supplied in a future edition.

CONTROL OF ANOPHELES.

Mosquito Surveys: A Handbook for Anti-Malarial and Anti-Mosquito Workers. By MALCOLM E. MACGREGOR, Entomologist, Wellcome Field Laboratory, Wisley. London: Wellcome Bureau of Scientific Research. 1927. Pp. 282. 15*s.*

A Short Illustrated Guide to the Anophelines of Tropical and South Africa. By ALWEN M. EVANS, M.Sc., Lecturer in Entomology, Liverpool School of Tropical Medicine. University Press of Liverpool, Ltd. 1927. Pp. 54. With 12 plates. 9*s.* 6*d.*

MALARIA is unlike the majority of diseases, in that its epidemiology and control differ greatly in different parts of the globe. This is mainly due to the fact that there are some 30 species of *Anopheles* suspected of being carriers in one country or another; each of these has its peculiar seasons, breeding places, and habits. It follows that the control of the vector and the disease depend on knowledge of local conditions and on methods which may not be generally applicable.

Mr. MacGregor has written an account of the mosquitoes of Mauritius and Rodriguez, and has used it as the foundation of a general account of anti-mosquito measures. The result is not very successful. These islands are oceanic, with a small and specialised fauna. Much space is devoted to forest species, which breed in rot holes, and have no relation to human beings. The purpose of the book is to provide information useful to field workers who have to study the control of *Anopheles* and other mosquitoes. The more general parts of the text are clear and elementary, but parts of the book are extremely specialised, and would only be appreciated by a competent medical entomologist; we refer to some of the details relating to the anatomy of Culicine larvæ, and in particular to the reprinted Key to the Culicine Genera of the World, by Edwards. The best points of Mr. MacGregor's book are the practical notes on breeding and laboratory technique, a matter on which the author is a master, and the account of the common domestic Culicines, *Culex fatigans* and *Aëdes argenteus*, which receive insufficient treatment in most works.

Miss Evans in her description of the species of *Anopheles* found in Africa south of the Sahara gathers together the results of much previous work, done from the Liverpool School of Tropical Medicine and elsewhere. Her book will be found valuable to many field workers, whose duty it is to discover which species of *Anopheles* is harmful, where that species breeds, and how best it may be controlled. The entomological aspects of malarial control in Africa are complex, because there are more than 30 species of *Anopheles* in the continent, and because it is not yet known whether some of them are vectors of malaria or not. Miss Evans's book is admirably illustrated with line drawings and half-tones, executed by the author, and with photographs of breeding places of some of the more important species. Its value to those living out of Europe would have been increased had the work of earlier writers been abstracted more fully.

X RAY AND RADIUM IN THE TREATMENT OF DISEASES OF THE SKIN.

Second edition. By GEORGE M. MACKEE, M.D. Professor of Dermatology, New York Post-Graduate Medical School. London: Henry Kimpton. 1927. Pp. 788. 45*s.*

THE keynote to this excellent work is repeatedly emphasised in the preface—X rays and radium must be used or directed by a man who is not only a dermatologist, but also a radiologist. The author holds that "too many physicians use X ray and radium with no more knowledge of these agents than that possessed by a technician," and protests that "without a training in radiology the dermatologist cannot be resourceful in diagnosis, therapy, or research nor can he use X rays and radium intelligently." These agents are not a panacea that can be used ignorantly and indiscriminately, and there is little doubt that the unskilful application of radiations has frequently brought the methods employed into disrepute. Dr. Mackee has planned his book on broad lines and has included in it the ground work of physics essential to the intelligent application of radiations. He is a clinician by profession and a research scholar by nature. He shows constantly that he is discontented with empirical dicta and would like to turn to laboratory experiments to investigate further the unexplained results obtained by himself and others.

The chapters dealing with protection and allied subjects are full of practical wisdom. A specially interesting chapter is that on idiosyncrasy, a subject of great importance, not only in therapeutic, but also in diagnostic work. Much information gathered from the foremost American radiologists has been compressed into this short chapter, and the author states that "the use of the term idiosyncrasy has decreased in about direct proportion to the improvement in technique and increase in therapeutic biological knowledge."

In 43 concise and orderly chapters the author discusses his own views with full regard to those held by workers who differ from him. He has succeeded in compiling a book which is not only readable but valuable to dermatologists and to all who study radiology.

INTERNAL MEDICINE.

Lehrbuch der Speziellen Pathologie und Therapie der inneren Krankheiten. By Prof. Dr. A. STRÜMPELL. Twenty-sixth edition. Revised by Prof. Dr. C. SEYFARTH, Assistant to the Medical Clinic of the University of Leipzig. Leipzig: F. C. W. Vogel. 1927. Vol. I., pp. 872; Vol. II., pp. 982. M.58 for the two vols.

A GENERATION of medical students and practitioners has been brought up on Strümpell's text-book of general medicine since it first saw the light in 1883, and now, three years after the original writer's death, the book has been brought fully up to date by Prof. Seyfarth. The first volume, which appeared in 1926, dealt with the acute infections, respiratory, circulatory, and alimentary disorders. The second volume now before us deals with diseases of the urinary and locomotor systems, of the blood, and endocrine glands, with disorders of metabolism, and concludes with a section of 500 pages on the nervous system. Three appendixes take in poisonings, prescriptions, and spas respectively. Illustrations are abundant and good although the scarcity of skiagrams is rather striking; the few that are given are printed on special plates with good effect. Treatment by physical methods receives less attention than it deserves and diathermy appears nowhere to be mentioned. But these are small drawbacks which can be rectified on the next revision, and the book remains one of the best manuals of special pathology and therapy in any language.

DISEASES OF CHILDREN.

Aids to the Diagnosis and Treatment of Diseases in Children. Sixth edition. By the late JOHN MCCAW, M.D. Revised by F. M. B. ALLEN, M.D., M.R.C.P. London: Baillière, Tindall and Cox. 1927. Pp. 330. 4*s.* 6*d.*

THE revision of this unit of the "Aids" series, written by the late Dr. McCaw, has been carried out by Dr. Frederick Allen. He has met with complete success in his attempt to keep the volume up to date, and from such important examination standpoints as ætiology, classification, and symptomatology, it should provide the student with the greater part of his necessary equipment. Dr. Allen states in the preface that he has endeavoured to increase the utility of the book by reducing the space allotted to treatment. He has done this rather too drastically, barely enough provision being made in this branch of pediatrics for examination requirements. For instance, the process of simplification has left the section on infant feeding without any definite scheme for modification of milk, the reader being referred to other text-books. With this possible exception the subject is very adequately covered, and, if used for the purpose for which it is best suited—namely, revision—this volume of the series should continue to be of great assistance to those preparing for qualifying examinations.

NUTRITION.

Feeding and the Nutritional Disorders in Infancy and Childhood. By JULIUS H. HESS, M.D., Professor of Pediatrics, Illinois University. Philadelphia: F. A. Davis Company. 1927. Pp. 566.

THIS well-known work of Prof. Hess's has been for some years representative of the most thorough-going attempts to apply the results of biochemical research to the everyday practice of pediatrics, and has made a strong appeal to those who prefer to approach the subject from the angle of pure physiology. In the new edition the author's method has scored further successes, for not only has the process of correlating theoretical considerations with practical therapy been extended in many directions, but a degree of simplification has been achieved which cannot fail to increase its popularity. In the chapter on artificial feeding Prof. Hess propounds a system in which an absolute relationship is maintained between the quantities of the food elements and the requirements of the infant per pound and kilogramme. He applies this system to the method of feeding by simple dilutions of cow's milk with added carbohydrate, and presents a scheme which is easy to apply, and free from the complicated formulæ which have rendered percentage and calorie feeding distasteful to many practitioners. One and a half ounces of milk per pound of body-weight is taken as the minimum requirement of a normal infant; a minimum addition of one-tenth of an ounce of carbohydrate per pound is made, and is supplied in the form of cane sugar up to a maximum of 1½ oz. in the day. If the carbohydrate requirement exceeds this amount it is met by the use of cereals. No fat is added to the mixture. A new chapter on cœliac disease contains a review of recent work on the ætiology and treatment, and embodies the late Prof. T. Howland's method of dieting with protein-milk as a basis. Minor additions have been made to the accounts of rickets, athrepsia, acidosis, and other disorders which involve dietetic factors.

A TEXT-BOOK OF THERAPEUTICS.

Including the Essentials of Pharmacology and Materia Medica. Seventh edition. By A. A. STEVENS, A.M., M.D., Professor of Applied Therapeutics in the University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1927. Pp. 758. 30*s.*

THE last decennial revision of the United States Pharmacopœia having become effective in January, 1926, the appearance of the seventh edition of this work is of some special importance in America. The book consists of two parts, the first being a description of all kinds of remedial measures, the most important of which is the long and well-tabulated section on drugs which occupies 500 pages. This section also contains references to such other forms of therapy as massage, electricity, blood transfusion, spinal puncture, and heliotherapy. The second part is a very comprehensive index of treatment.

The drugs are arranged in the usual order—that is to say, their physiological action determines their place, as in other well-known text-books such as that of Sir William Hale-White. In this edition many drugs find a place for the first time. Barium chloride in heart-block, ephedrine in asthma and hay fever, butyn in local anæsthesia, sulpharsphenamine in syphilis, and two other organic compounds containing arsenic, tryparsamide and stovarsol, are among these. The methods of administering thyroid gland are excellently described; the fresh gland is hardly mentioned, the dried extract and thyroxin in carefully adjusted doses being preferred. Insulin is fully discussed; its possible use in cases of non-diabetic acidosis is mentioned, for example, in eclampsia, post-operative acidosis, and cyclic vomiting. Insulin shock is described. Subcutaneous or intramuscular injection of Collip's extract of parathyroid is recommended in acute or chronic tetany, oral doses having been found ineffective; in other conditions—e.g., in eclampsia and paralysis agitans—the extract is useless. Potassium bismuth tartrate is recommended intramuscularly for tabetic pains and chronic syphilitic meningitis; mercuric oxycyanide as a germicidal solution in dilution of 1 : 1000; novasurol (merbaphen) as a powerful diuretic in œdema due to cardiac and renal disease; hexylresorcinol in certain cases of infection of the urinary tract, and gentian violet, brilliant green, and acriflavine as powerful antiseptics with low toxic properties. The value of scarlet fever and erysipelas antitoxins is judiciously appraised, and there is a good account of non-specific protein therapy. Transfusion of blood and heliotherapy are not dealt with in great detail.

The last part of the book consists of applied therapeutics. Accounts of general and dietetic methods of treatment will be found in their proper places, but treatment by drugs is chiefly stressed. In many sections, such as that on diseases of the respiratory

tract, useful formulæ may be found. The short section on diseases of metabolism deserves special mention, containing not only a useful diet for cases of obesity, but, much more important, a very complete analysis of the value of most foodstuffs. This analysis will help the practitioner to construct a diet in diabetes or to replace in the dietary one constituent by another.

The volume will be useful to the student of pharmacology, to the clincal clerk, and to the practitioner.

TEXT-BOOK OF BACTERIOLOGY.

By WILLIAM W. FORD, M.D., Professor of Bacteriology, School of Hygiene and Public Health, Lecturer on Hygiene, School of Medicine, Johns Hopkins University; Member State Department of Health of Maryland. London and Philadelphia: W. B. Saunders Company, Ltd. 1927. Pp. 1069. 37*s.* 6*d.*

THIS book is described as "an attempt . . . to give complete and accurate descriptions of the micro-organisms commonly encountered in medicine, comparative pathology and hygiene, and public health . . . and is intended primarily for the medical student and the medical bacteriologist." In our view its undoubted value lies not in the account of the common micro-organisms which the medical bacteriologist encounters, but in the description of the rarities which are omitted from the majority of standard text-books and can be found only after laborious search through the literature. Dr. Ford names, for example, 53 species of actinomyces, most of which are certainly not "commonly encountered"; the list may indeed appal the medical student—but perhaps Dr. Ford uses the term student in its broadest sense. It is chiefly the busy trained bacteriologist who will profit by the work, for it gives him the features of many varieties of organisms in a form easy of access. From this point of view the book is most useful. The sections on general bacteriology are somewhat inadequate; notable omissions include the whole question of "rough" variants. The brief account of technique might have been left out of an advanced text-book of this nature, as might also the picture of a microscope; the student capable of tackling 53 actinomycetes is at least acquainted with the external appearance of a microscope.

Systematic bacteriology occupies roughly three-quarters of the book, and the rest is devoted to immunity and infections of doubtful origin. Obviously it has been impossible for the author to verify more than a fraction of the work he quotes, some of the species included having been described on one occasion only, and this point must be remembered by those who use his book for reference. It is undoubtedly a valuable contribution to bacteriological literature. Those who have in the past found Macé's treatise a source of help in time of trouble will find here an up-to-date substitute for that now rather antiquated work.

TO-DAY AND TO-MORROW.

(1) *Galatea or the Future of Darwinism.* By W. RUSSELL BRAIN, M.D. Oxf. London: Kegan Paul, Trench, Trübner and Co.; New York: E. P. Dutton and Co. 1927. Pp. 95. 2*s.* 6*d.*

(2) *Archimedes or the Future of Physics.* By L. L. WHYTE. 1927. Pp. 96. Same price and publishers.

THESE two books are recent additions to the "To-day and To morrow" series which since the date of its commencement and through some 50 little books has provided us with much stimulating material, surveying modern thought in many departments of life, always with courage and often with humour.

(1) In "Galatea" Dr. Russell Brain attacks neo-Darwinian theories with closely packed arguments. He finds biology to be reaping harvests rendered available by new mechanistic methods, but points out that mechanism has been shaken to its foundation by the discovery that time and matter are "not the all-sufficient raw material of the universe but merely products of the mind's attitude towards the four dimensional world of point events"; and he here makes the apt comparison that Darwin is the Newton of biology, which still awaits an Einstein, the philosophic approach to scientific problems being as important as what is held to be the strictly scientific method. In his opening words he presents rather cruelly the course of evolution, according to neo-Darwinism, through a parable, likening mankind to a company of persons leaving London with destinations decided on at random from a time-table, and repeating this process on reaching their first destinations, it being postulated that all who were unfortunate enough to hit upon a second town, which had no station on the particular railway line as the first town, should be executed. It is a fact that this parable illustrates the criticised tenets rather happily, as giving the appearance of an orderly progress where there is no rational mode of locomotion. We recommend Galatea cordially to our readers; no résumé of its contents could be much shorter than the volume itself.

(2) "Archimedes" may well be read in juxtaposition to "Galatea," and the deductions in each may be easier to follow if the reader consults another volume in the series entitled "Gallio," in which J. W. N. Sullivan writes on the tyranny of science. Mr. Whyte's little volume is an appeal to thinkers that they should discard unjustifiable limitations in scientific thought, and should combine to discover what he believes to exist—namely, a single system of natural law which may cover the realms both of matter and life. He suggests in his book the definite line of advance for physics, pointing out that we stand at the eve of a new epoch, when physics, biology, and psychology are converging towards a scientific synthesis of unprecedented importance with results that may elucidate the problem of life—for no less than this is the outcome which he foresees of the latest inquiries into the fundamental electrical processes underlying radiation and chemical combination. As was said in respect of "Galatea," and as we have said in respect to other contributions to this brilliant series, attempts to summarise would be defeated by the author's brevity and compressed form of argument.

JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXIV. October–December. — In a paper entitled an Investigation on the Analysis of Human Milk, Dr. Bernard Myers reports on 184 separate analyses carried out at the Children's Clinic, Marylebone-road, of the milk of 84 nursing mothers, whose ages ranged from 16 to 30, the average age being 22. The average analysis showed protein 1·58 per cent., fat 3·85 per cent., lactose 6 per cent., and the caloric value per ounce 18·95. The last third of the milk contained the highest percentage of fat. Although a large number of analyses showed fairly similar results, there was in many instances a distinct variation, especially as regards the fat content and the protein, which within certain moderately wide limits remained normal. The milk of a nursing mother was apt to vary to some extent from day to day, but unless this variation was excessive it did not affect the infant. In conclusion Dr. Myers maintains that for the purpose of an analysis or caloric value calculation the middle third or the whole of the milk in the breast should be used.—In continuation of his paper on Insulin Treatment of Diabetes Mellitus in Children, Dr. K. U. Toverud, of Oslo, discusses the carbohydrate tolerance during insulin treatment as affected by control of the diet, the occurrence of infections, the presence of acidosis, muscular exercise, and increase in weight, and gives an account of the post-mortem examinations. The histories of the 47 cases on which the paper is based are appended, together with some striking photographs of some of the children before and after insulin treatment.

THE LANCET.

LONDON: SATURDAY, JANUARY 21, 1928.

DEATH CERTIFICATION.

IT is a common opinion that the methods of death certification might be improved, and many suggestions to that end have been made by doctors and statisticians, statisticians who are not doctors, and practitioners who, without the implications of mass figures in their minds, none the less desire to record on a State document accurate evidence. In recognition of all this, the Joint Committee on the Nomenclature of Diseases appointed by the Royal College of Physicians of London, in view of the next decennial revision of their report, has directed particular attention to the subject of death certification, and in their meetings a general feeling has been reflected that the young medical man enters into practice without fully appreciating the importance that attaches to accurate death certification. For this there seems one main reason. Of all the duties falling to the lot of the medical man there is none for which so little instruction is provided in his student days, this being apparently due to the fact that the high public significance of the responsibility has been overlooked. Can this be due to a sort of belief that the documents will always be so defective that the returns must be of little value? If this is the case it would seem that two things are overlooked in such an easy mental attitude; first, that every step ought to be taken to help the practitioner to make as accurate a return as possible so that these returns should obtain value; and secondly, that the returns as they at present exist, and with their admitted inaccuracy, are of real public service.

In the figures, as we now have them, there may be many errors, but in so far as these errors are due to carelessness and not to prejudice they cancel each other, so that correlations between disease and mortality emerge whose truth cannot be gainsaid. For example, while the statistics, as supported by death certificates in reference to alcoholism and syphilis, are regarded commonly as particularly untrustworthy, none the less these figures give a valuable picture of what is actually occurring. Employing the form of certification introduced with the International List in 1910 which is valid up to 1920, we find a fall in the alcoholic death-rate proceeding steadily, and even very rapidly in 1918 and 1919, under the influence of war conditions. In 1920 the rate rose, for the population was spending its war bonuses and feeling rich, but even so it reached but a little more than one-third of what it had been in 1910; in fact the war restrictions on the consumption of alcohol reduced this form of mortality by 81 per cent. in the four years, 1914–18, while the reaction of 1920 was reflected by a mortality-rate which attained to only about one-fifth of that before the war. Whatever, therefore, the practical value of the alcoholic death-rate may be as an accurate measure in detail of the extent of this form of mortality, it is of great value as an indication of the effect of a public movement. The accuracy of the alcoholic death-rate, it may be admitted, can be gauged from information obtained from many sources, while that from syphilis and its known sequelæ cannot be checked in this manner. We do, however, know that, while the mortality in association with venereal disease had been falling before the war, it rose rapidly during its progress, so that in 1917, when the control of venereal disease became the subject of State interference, it was at its maximum. To-day the mass figures show that the mortality-rate in syphilis and associated disease has declined from that ominous point, and they can fairly be regarded as an index of progress. If this can be said of returns which in the nature of things would always represent a maximum of unreliability, because of the many reasons for concealment, we may feel sure that under other headings of classification imposed by revised nomenclature the results can be accepted with less question. Indeed, there is no reason to doubt that mortality statistics, however imperfect, already provide preventive medicine with information of the first importance, and as medical training grows more scientific, and as medical knowledge expands in scope as well as improves in definiteness, this importance will grow. But admittedly, then, the task of filling up the actual form, imposed on the practitioner, will become more complex, and this is foreshadowed by the latest form of death certificate, where the practitioner is invited to state first the immediate cause of death and then, proceeding backwards, the morbid conditions which gave rise to this cause. Now the general rule in the office of the Registrar-General is that if several causes of death are mentioned in association on a death certificate a single cause is selected for classification, and at once a difficulty is introduced, in the ascertainment of which is the one that should be recorded. For example, a death may be certified as due to (1) heart failure, (2) myocardial degeneration, and (3) bronchitis; or as (1) bronchitis, and (2) heart disease. If it is a general rule that cardiac affections are selected for tabulation in the Registrar-General's office in preference to pulmonary affections, both these sequences of events will be allocated to heart disease. It was in order to provide a remedy for this state of affairs that the new form of certificate was framed; that is to say, it was designed to secure a definite expression in connexion with the various causes of death, so that the official tabulator might be able to follow the certifier's view of the sequence of events culminating in death. As soon as this view is clearly expressed in a large majority of certificates that reach Somerset House, the Registrar-General will no doubt feel at liberty to discard his own method of selection by rule.

It is certain that the considered views of the Joint Committee will be brought to the attention of the General Medical Council, and, as the educational authority of the medical profession, that body may hold that more assistance in regard to the matter is due to medical students at the latter end of their curriculum. The Council has done useful work for the profession and for the public in its rigid insistence on the accuracy of medical certificates of all sorts. The death certificate, more important from the public point of view than any document which requires a medical sign manual, is admittedly a delicate form to execute, and the considerations that should be before the signatory's mind might well be introduced to him before he is called upon to act professionally.

A YEAR'S EXPERIENCE OF DENTAL BENEFIT.

THE amended scheme for the administration of dental benefit under the National Insurance Acts has been in force for a little over a twelvemonth, and it is now possible to take stock of its working as it affects the dental department of a general hospital. Three categories of insured persons receive dental treatment at the hospitals—namely: (1) patients referred by the honorary medical staff of the hospital; (2) patients referred by practitioners because they require treatment which cannot be given by a private dentist; and (3) emergencies. All other insured persons are referred to outside dentists. The chief difficulty met with in applying the insurance scheme to these three categories is occasioned by the provision that an estimate of the work required should be submitted to the approved society for approval *before* treatment is begun, and by the onus placed on the patient to make a personal application to the society. In categories (1) and (2) it is often a question of extraction of one or more teeth before a course of medical treatment is started or an operation performed; delay in many cases would affect adversely the prescribed treatment. Category (3) must receive immediate attention as a matter of common humanity. The clause allowing treatment to be undertaken up to the value of 10*s.* without previous submission of an estimate does not provide effectively for the situation, as it only allows for the extraction of one tooth under nitrous oxide gas, and the treatment may only be given if the patient has already obtained a dental letter. In the case of the smaller societies whose members are in personal touch with their secretaries, such a letter can generally be had immediately, but where it has to be obtained from a large society through an agent, the delay is often considerable. The submission of estimates, moreover, entails clerical work on the part of the honorary dental staff for which they can ill spare the time, while a lay person can only furnish a statement of the work actually performed. As regards the proviso for personal application by the patient, even where the society allows the hospital to treat first and claim afterwards, it is difficult or impossible to induce patients whose pain has been eased and whose treatment is finished, to sit down and write a letter making a claim the import of which they probably do not understand.

Two of the large approved societies and several smaller ones have now recognised these difficulties and sanctioned schemes which meet the point of view of the hospital. A form is issued to the almoner at her request and the grant is made on her statement of the work done, provided she obtains the patient's signature, about which there is generally no difficulty, as most patients are willing to sign their names to help the hospital. On the other hand, three large societies still adhere to the letter of the law and refuse to make grants for dental treatment without the submission of estimates. At St. Thomas's Hospital we are informed that 91 members of one society, apparently entitled to dental benefit, were treated during the year without any recompense to the hospital. Twenty-two societies have coöperated with the hospital in giving dental treatment and have contributed £52 9*s.* 9*d.* during the year for 63 patients, an average of 16*s.* 8*d.* per patient. The total number of insured persons apparently entitled to benefit was 330, and assuming that 20 per cent. of these, on investigation, should prove not to be so entitled, payment should still have been received for about 264 instead of 63, and taking the average individual payment at 16*s.* 8*d.*, about £220 should have accrued to the hospital. Apart from these special difficulties in the application of the scheme to hospital practice, there are other objections which arise from the present lack of standardisation. In the first place, there are still a few societies which provide no dental benefit at all. The majority of them pay the whole cost of treatment according to the agreed scale issued by the British Dental Association and the Public Dental Services Association, but a few societies demand from the member a portion of the cost, generally 25 per cent. The grant for dentures is far from uniform, and although 50 per cent. of the total cost is now the rule there are still societies which reimburse the whole cost and others less than one-half. Complete suspension of benefit may occur at any moment, for the societies put aside a certain sum annually for this purpose, and if this sum is spent before the end of the year dental benefit ceases until the following year. Two of the largest societies had, in the autumn of 1927, used up the allotted funds. These variations involve real unfairness to the patients who have all paid their quota at the same rate, and engender in them a sense of soreness and bewilderment. At the same time they make the administration of dental benefit from the hospital side both difficult and unsatisfactory, and involve a vast amount of correspondence. On the other hand, the adoption of a standard dental letter is a step forward, and the more progressive societies are acting more and more on standardised lines.

A FAMOUS MEDICAL JOURNAL.

THE New Year issue of the Münchener Medizinische Wochenschrift is a Festschrift in celebration of the seventy-fifth birthday of the journal, for the first number appeared on Jan. 7th, 1854. It was from the start the property of a standing committee of Bavarian doctors, and, although modest in size, its scope was so ambitious as to incur pessimistic criticism from Rudolf Virchow who was then nothing more than an official medical officer to one of the smaller divisions of Bavaria. Like the birth of other great medical journals, the happy event had been preceded by a number of miscarriages. The Medical Correspondence Sheet founded by Dr. H. Eichhorn in 1840 survived for barely ten years, while the Medico-political Sheet of Dr. v. Jan ran for less than a year; but it was endeavours of this kind which encouraged the firm of Christian Kaiser to issue a journal which bore for 30 years the title Medical Intelligence Sheet, Organ of Bavarian State and Public Medicine, the financial success of which was ensured by the decision of the Government, two years after its foundation, to distribute it officially to all local authorities and their medical staff. This official relation lasted until 1874 when the conduct of the journal came into the hands of an independent group of medical men, headed by Otto von Bollinger, under whose influence the youthful BERNHARD SPATZ was appointed in 1885 to the editorial chair, and a year later the journal was rechristened under its present name. It was in 1890 that the business side of the paper was taken over by the present publisher, J. F. LEHMANN, in whose hands it rapidly developed from a provincial medical journal into one of worldwide importance. Financial difficulties were then a thing of the past right up to the post-war currency inflation, when the journal

lost its accumulated capital, but was just able to carry on. The military supplement was distributed gratis to all medical officers in the field from 1914 to 1917, when the paper famine made it impossible, and during the last 25 years, in spite of all these difficulties, the sum of nearly 250,000 marks has been allotted out of profits in grants towards scientific and benevolent purposes.

The first three volumes of the journal, which are now difficult to obtain, throw many interesting sidelights on contemporary medical history, some of which are dealt with fully in an introductory article by Prof. Hermann Kirschensteiner which appears at the front of the festal issue. From it we learn that 50 German medical men voluntarily took part in the Crimean War of 1855, of whom 10 died on service and only 6 returned unscathed. The early numbers bear witness to a vigilant struggle against the homœopathic influence which was then widely spread throughout the kingdom. Paris was still the favourite centre of post-graduate study for Bavarian doctors; and there is an instructive passage in a Paris letter dated 1856, giving an account of hospital pyæmia with the query: "Where is the poison? is it in the hospital air? Do the hands of the surgeons carry it? I would give my life to buy these secrets." Semmelweis had already published his early work, but it was B. Breslau who pleaded in an issue of 1854 for strict separation between the healthy and the sick puerperium, for he had seen that the mortality in childbirth which amounted to 4 per cent. in Paris and 5 per cent. in Vienna, was only 1 per cent. in Dublin with its cubicle system. The early days of the journal saw the rise of Pettenkofer to fame in connexion with the second outbreak of cholera, which killed 3000 of the 5000 persons attacked, although it seems that no Munich doctor died of it. Pettenkofer set out in the journal his subsoil theory of causation which for so long held the field. Another historic discussion concerned the infectious character of secondary syphilis, which was then generally denied. A certain Dr. Hübner had the misfortune to infect a number of vaccinated children with syphilis; he was sentenced to six months' imprisonment and discharged the service, although a number of his colleagues were prepared to assert that infection could not be conveyed in this way. These issues also contain the record of the third case of Cæsarean section, carried out by Rothmund; the child survived, but, as in both previous cases, the mother died. In these early days it is surprising to learn that the medical profession in Bavaria was already regarded as overcrowded. In the whole kingdom there was one doctor to 3784 persons; in Munich itself the proportion was 1 to 1050, and in Würzburg 1 to 619, not reckoning the professorial staff. The mortality among them was terrible. In 1855 the average age of the practising doctors was only 44·4 years; no more than 29 per cent. of the profession lived to 50 years, and 9 per cent. to 60 years. Medical practice at this time was to all intents a State service; the newly qualified man could not choose where he would settle. He was nominated to a district where there was a vacancy, and permission to practise in Munich itself was only granted after three years' rural experience—the so-called triennium rusticum. The experience of this system was not happy, especially in Nassau where it was most strict, and through the influence of Karl v. Pfeufer the State control was set aside entirely in 1865. So much for the early years. In its later history the journal contained the account of Pettenkofer's self-experiment with cholera vibrios in 1892, the Nobel prize lecture of Ehrlich in 1909 on the partial functions of cells, the most part of his early work on salvarsan, and his exposition with Gruber of the side-chain theory. Orthodiagraphy was described in the journal by Moritz in 1900, and in 1903 Albers made the first communication on the risk to the genital glands from exposure to X rays. The journal was also the first to take hypnosis seriously by the publication in 1894 of Forel's work on treatment by its means.

In another part of the festal issue, and printed in the small characters in which the Editor modestly conceals his own hand, is an interesting apologia for the advertisement part of the Munich medical journal. Many doctors, he says, have so little understanding for its value that they are actually hostile and regard this section as an unworthy bedfellow of the scientific part. The hostility, he recognises, is directed not so much to the advertisements in themselves as to the over-production of drugs. It would, however, he reminds German doctors, be thankless on their part to overlook how much they owe to the chemicopharmaceutical industry, if only for the reason that without their collaboration the size and compass of the journal would have to be considerably reduced. He takes for granted a strict censorship by the medical press of the advertisements which are accepted, and first and foremost the refusal of any influencing of the text by the advertising firms. This censorship has for long been assumed by the Editor of the Munich journal and has worked well. With these essential postulates, flourishing advertisement columns fill an important place in the framework of the journal, putting its readers in touch with information and announcements which cannot appear in the text, with new appearances in the book and instrument markets, with the latest information about baths and drugs, and providing a useful balance to devote to relief of medical suffering, to the furtherance of scientific work, to the support of medical libraries, and to supplying impecunious German doctors abroad with medical literature. Certain it is that collaboration of editor and publisher in the case of the Münchener Medizinische Wochenschrift have brought forth one of the premier medical journals of the world, and we offer Dr. SPATZ and Mr. LEHMANN our homage.

Annotations.

"Ne quid nimis."

VITAL STATISTICS FOR 1927.

THE Registrar-General has issued a provisional statement of the figures for birth-rate, death-rate, and infantile mortality during the year 1927.

—	Birth-rate.	Death-rate.	Infant mortality-rate.
England and Wales ..	16·7	12·3	69
107 county boroughs and great towns including London	17·2	12·3	71
155 smaller towns ..	16·5	11·4	68
London	16·1	11·9	59

The smaller towns are those with an estimated population in 1921 of 20,000–50,000. The death-rate for England and Wales relates to the whole population, but that for London and the two groups of towns to the civil population only. Birth-rate and death-rate are per 1000 population, infant mortality-rate per 1000 births.

The Registrar-General remarks that the birth-rate is 1·1 per 1000 below that of 1926, and is the lowest rate recorded since the establishment of civil registration. The death-rate is 0·7 per 1000 above that of 1926; the excess being due to the high mortality of the first and fourth quarters of the year. The infant mortality-rate is equal to that of 1923, the lowest on record; the rate in 1926 was 70 per 1000 births. These provisional figures, which are not likely to require substantial modification, have been issued for the information of medical officers of health.

AFTER THE FLOOD.

THE conference held last Monday afternoon at the Ministry of Health to review the situation resulting from the recent flood disaster in London was attended by representatives of the London County Council, of various Government departments, and of the riparian authorities. Sir Kingsley Wood, who presided, explained that the conference had been called at the instance of the Prime Minister and its immediate duty was to settle what action should be taken to prevent a repetition of a disaster which had undoubtedly been brought about by a peculiar combination of circumstances. On behalf of the London County Council, Mr. Gatti stated that the Council's only responsibility was based on an Act of 1879, under which the Council may require owners of riverside premises to carry out flood prevention works to its satisfaction, or, in default, itself execute the works and recover the cost. The height of such works had originally been fixed by the Metropolitan Board of Works at 17 ft. 6 in. above datum-line, and this was raised to 18 ft. after the record tide of January, 1881. Since that date, 47 years ago, the tide had only once equalled and never exceeded 17 ft. 6 in.; on Dec. 26th last it reached three inches short of that figure, that is to say, the second highest point on record, without producing any signs of flooding. Existing works, he said, had now been so seriously damaged that occupation of basements in low-lying areas would be attended with danger at spring tide for some while ahead. The Council had already undertaken to institute a survey of the whole of the river defences. Speaking on behalf of the Port of London authority, Lord Ritchie said that, while normally in the course of the last hour of a flood-tide the river did not rise more than 1 ft., it actually rose 2 ft. in the last hour of the tide on the morning of the catastrophe. The desirability of raising the level of the banks required, he thought, careful consideration in view of the large expenditure involved and the improbability of the recurrence of such a tide. In any case as the work must take years to complete, it was desirable to consider whether the public could not be warned of the approach of a high tide. Any warning, to be effective, would have to originate outside the estuary of the Thames, and inquiries were on foot to see if information of the approach along the coast of a phenomenal tide could be obtained in sufficient time to give warning through the police or other authorities. Lord Desborough, on behalf of the Thames Conservancy, said that he thought the height of the tide was not greatly affected by the volume of water coming down from the upper reaches of the river. The recent disaster was due rather to the combination of a north-westerly gale with an exceptionally high flood tide. Alderman Ben Smith, M.P. for Bermondsey, pointed out that the existence of a 71 minute delay between high tide at the Isle of Dogs and at Teddington should have allowed time for warning to be given. He also remarked on the lamentable state of 600 families in Rotherhithe whose homes had been destroyed by creosote. Mr. Gatti, in reply, stated that the London County Council did not repudiate its statutory responsibility, but he contended that the adequacy of the river defences had been proved by the fact that on Boxing Day the second highest tide on record for 60 years was experienced without any signs of flooding. The conference, before adjourning, decided to set up a small subcommittee under the chairmanship of an assistant secretary of the Ministry of Health, to which the various suggestions would be referred.

SIR MACKENZIE CHALMERS.

A MEMORIAL service for Sir Mackenzie Chalmers, who died on Dec. 22nd, 1927, will be held at the Temple Church on Tuesday afternoon, Jan. 31st, at 4.45 P.M. We are reminded by this announcement of the services which, throughout an extraordinarily full official life, Sir Mackenzie rendered to the cause of medicine. He was consecutively a member of the Indian Civil Service, a Counsel to the Board of Trade, a county-court judge, a Commissioner of Assize, and a Law Member of the Viceroy's Council in India; then he was appointed, some quarter of a century ago, First Parliamentary Counsel to the Treasury, and finally, until retirement in 1908, Permanent Under Secretary of State for the Home Department. In this capacity he was a member of a Royal Commission on Vivisection, of a Departmental Committee on Coroners and Deaths under Anæsthetics, and of the Sleeping Sickness Committee, while later he served as chairman of the Committee on the Standardisation of Biological Drugs. While these had been his various responsibilities towards medicine in an official capacity, his private interest in our profession was well displayed in his chairmanship of the London Fever Hospital, in whose cause he was untiring. Medicine owes a real debt to Mackenzie Chalmers.

PROFESSIONAL SECRECY.

AN interesting report on medical confidences has just been issued in France,[1] where it appears that the accepted tradition of absolute professional secrecy has been threatened by a recent decision of the Conseil de Préfecture of Châlons-sur-Marne (May 27th, 1927). The committee which has produced the report calls upon the profession to protest vigorously against claims which would seem to demand disclosure of the diagnosis of diseases treated at patients' houses. The report insists that the legal position should remain where it stood after the decision of the Cour de Cassation in the Watelet case in 1885. No more vigorous defence of the confidential relations of doctor and patient has been made in England, but the English reader has to remember that the position in France rests not upon a professional tradition partially recognised by the law courts but upon an express enactment in the French penal code. This enactment (Article 378) is not set out in the recent report but deserves attention.

"Les médecins, chirurgiens et autres officiers de santé, ainsi que les pharmaciens, les sages femmes et toutes autres personnes dépositaires, par état ou profession, des secrets qu'on leur confie, qui, hors le cas où la loi les oblige à se porter dénonciateurs, auront révélé ces secrets, seront punis d'un emprisonnement d'un mois à six mois et d'une amende de cent francs à cinq cents francs."

It would appear to follow that secrecy must be maintained even after the patient's death, whereas in English practice death is regarded as lessening the duty of secrecy. Under English law, indeed, the patient's remedy in this respect (for breach of professional secrecy) dies with him. It is noteworthy that the French committee's report contains objections even to the disclosure of information regarding the cause of death. Such violation of secrecy, it points out, has grave inconveniences; the doctor, wishing to protect the dead patient's memory, inclines towards a misleading diagnosis—cerebral hæmorrhage, for instance, instead of cerebral syphilis, or (where disclosure of diagnosis would amount to actually charging a party with a crime) peritonitis instead of abortion.

In England, where the absence of an all-embracing codification of the law has left so many matters a little indefinite, the position could not be put so high as in France where the profession can insist on the logical consequences of Article 378. When the Duchess of Kingston was charged with bigamy in 1776 and Cæsar Hawkins made the traditional protest against being required in his evidence to reveal something of which he had become aware in his professional capacity, Lord Mansfield summed up the position quite clearly. "If a surgeon was voluntarily to reveal these secrets, to be sure he would be guilty of a breach of honour and of great indiscretion;

[1] Bull. de l'Acad. de Méd., 1928, xcviii., 650.

but to give that information in a court of justice which by the law of the land he is bound to do will never be imputed to him as any indiscretion whatever." Mansfield was stating the law in the peculiar atmosphere of the criminal trial of a peer of the realm; the legal position was explained more fully and more recently in 1881 by Jessel, M.R., in Wheeler *v.* le Marchant, where the absolute privilege of the lawyer was contrasted with the limited privilege of the priest or the doctor. "It must not be supposed that there is any principle which says that every confidential communication which it is necessary to make in order to carry on the ordinary business of life is protected; the protection is of a very limited character and in this country is restricted to the obtaining of the assistance of lawyers as regards the conduct of litigation or the rights to property." It is this anomalous distinction between legal and medical privilege which surprises the English public and which will probably lead to some amendment of the law. The contradictory directions given by the State in the case of venereal disease clinics has naturally focused attention on the doctor's dilemma. "Keep absolute silence," say the Regulations of the Ministry of Health. "Tell us all you know," say the law courts. This is a contradiction which no departmental exposition can mitigate. In France, it seems, it is the department which is insisting upon the breach of secrecy.

ATROPHY FROM DISUSE.

ATROPHY of voluntary muscle from disuse has been generally accepted as a pathological fact for many years, and such disuse has by some been supposed to account fully for the wasting of muscles cut off from their central nervous centres, as well as for that of the muscles connected with ankylosed joints, and for wasting after fracture or prolonged immobilisation for any reason. But this view of the pathology of atrophy is not universally held, and those who rejected it have always been able to point to certain facts that cannot be accounted for in that way. The marked and permanent atrophy of the quadriceps, which follows on fractured patella, no matter how complete the anatomical restoration may be, offers a case in point. Again the muscular atrophy in bone or joint disease is much more rapid than that which follows on prolonged immobilisation for the correction of deformity and such-like. This wasting is not prevented by electrically stimulated contractions. Such atrophy is more extensive and lasting in adults than in children. All these and other considerations are set forth by Mr. N. Ross-Smith, surgical registrar to the Royal National Orthopædic Hospital, in a paper [1] in which he adduces the evidence afforded by the condition of a muscle which can never have done any work at all. Such is the so-called peroneus, more accurately named tibio-fibularis, which Mr. Ross-Smith has dissected and examined in two cases of congenital absence of the tibia and which Sir Arthur Keith has described in a case of Mr. R. Ollerenshaw's. As this muscle in all three cases had no insertion it was incapable of doing any work at all and was in a condition of more complete disuse than any normal muscle could be. Yet macroscopically and microscopically it was found to consist of normal healthy fibres and showed not the slightest sign of degeneration. In life the muscle had not been known to shorten. As the ages of the three patients ranged from 2 to 15 years there had been ample time for atrophy to show itself. The illustrations of Mr. Ross-Smith's paper show very clearly the histological and naked-eye appearances of the parts concerned. Despite experiments and investigations made in recent years, there is still evidently a good deal to be learnt as to the nutrition of muscle and much more extensive research will be necessary before we can hope to have a complete knowledge of the subject, to obtain which the very significant conditions found in congenital deformities will have to be taken into account. When we know all the factors concerned in the atrophy and restoration of disused muscles and the ways in which these factors exert their influence we may hope to be on the way to understanding the pathology of Volkmann's ischæmic paralysis to an extent that is beyond us at present. Such knowledge will probably prevent those catastrophes which are disastrous to the patient and most disconcerting to the surgeon, who is lucky if he escape an action at law and the payment of heavy damages as was demonstrated quite recently.[2]

CRYSTALLISED TUBERCULIN.

DURING the last 18 months a whole series of reports on the active principle of tuberculin have been published by Dr. Esmond R. Long and Dr. Florence B. Seibert [3] from the Sprague Memorial Institute and the Department of Pathology of the University of Chicago. Through coöperation with other organisations these workers have been able to avail themselves of enormous quantites of tuberculin—literally many gallons. The starting-point of the research was the growth of the tubercle bacillus on a protein-free fluid medium from which the bacillus was able to elaborate protein. The advantage of tuberculin produced in this way is that substances produced in the medium by the growth of the bacillus can be readily separated since all the constituents of the medium before growth are already known. Having obtained an almost unlimited supply of tuberculin in this way the authors proceeded to investigate the product by methods of dialysis, adsorption, enzymic action, and protein precipitation. Briefly recorded, the results of these investigations are as follows. The active principle of untreated tuberculin would appear to be a colloidal substance which does not pass through animal and vegetable membranes. This colloid gives all the usual protein tests and can be precipitated by acids at its isoelectric point, pH 4·0. Saturation with ammonium sulphate precipitates all detectable protein, this precipitate possessing the typical toxic properties of tuberculin. Proteolytic enzymes lessen or destroy the activity of this tuberculin in proportion to their power of splitting up the protein molecule; hydrolysis by hydrochloric acid also destroys activity in the same way. The next step was to obtain the protein constituent of tuberculin in a pure state. After extensive experiment Dr. Seibert [4] has succeeded in recrystallising the protein portion as many as 14 times, and has shown that this product, which is crystallisable into needles and burrs and is labile and unstable in water, has a greater potency than the original.

TYPHOID FEVER IN CHILDREN.

SINCE no epidemic of typhoid fever of any magnitude has occurred in any large town in this country during the present century, it seems to follow that much of what is written of the disease in modern text-books of pædiatrics cannot be based upon personal observations. Hence the value of a paper [5] by Dr. Saul J. Usher in which he describes 116 cases of typhoid fever in children under his personal observation in the Montreal epidemic of 1927, and 59 others to whose records he had access. The epidemic was transmitted by milk, which no doubt accounts for the large number of children under the age of 5 years who were affected. The onset was fairly rapid with fever, headache, loss of appetite, and general malaise as the most prominent symptoms. Gastro-intestinal symptoms were rare at the onset, epistaxis occurred in 17 per cent., mostly older children, while convulsions were noted only in one instance, an infant of 9 months. With the disease established the average temperature was 101°–103° F. in the majority of cases, while the pulse-rate varied between 90 and 120. Constipation was

[5] Canad. Med Assoc. Jour., 1927, xvii., 1486.

present in most patients; vomiting and loss of appetite were quite infrequent. Nervous symptoms were often noted during the course of the disease; in the younger children taking the form of restlessness, irritability, and fretfulness; in the older children of dullness, apathy, or listlessness. Delirium occurred during the height of the fever and rarely needed special treatment. In most cases the rash was scanty, seen chiefly over the abdomen and lower back; splenic enlargement was appreciable to the finger in 138 out of the total 175 cases. To turn to the laboratory findings: a positive Widal reaction was obtained in 91 per cent. of cases, and of these 59 per cent. were positive in the first ten days of the illness. Blood culture taken in 71 cases proved positive for the typhoid bacillus in 50 and completely negative in the remainder; in no case was paratyphoid A or B found. The cholesterol content of the whole blood was estimated in 15 acute and in 13 convalescent cases; in each case the cholesterol was found to be definitely increased, more so in the acute, and its fall to normal was very gradual after recovery. Complications were numerous and included suppurative processes such as otitis media and furunculosis. Intestinal hæmorrhage occurred in five cases, and perforation in four; ulcerative laryngitis in two cases. Only three patients relapsed and 12 died, a total mortality-rate of 6·8 per cent. For treatment, hydrotherapy was systematically employed, sponging being preferred. Diarrhœa never needed interference and constipation was dealt with by liquid paraffin. The original paper will repay study.

THE USES OF EPHEDRINE.

SINCE the rediscovery of the alkaloid ephedrine from the plant *Ephedra vulgaris* by K. K. Chen in 1923 there has been gradually accumulating a large volume of literature dealing with its use and effects in the treatment of asthma.[1] T. L. Althausen and I. C. Schumacher in a recent paper [2] report the use of this drug in a number of morbid conditions and summarise their personal experience with it in the treatment of bronchial asthma and hay fever. They point out that for 5000 years decoctions of the plant have been used in China as a diaphoretic and antipyretic, and at the time of the original discovery of the alkaloid, by K. Nagai in 1887, investigators were mostly concerned with its mydriatric properties. The present authors used it in nine cases of chronic vascular hypotension, giving it by the mouth in doses of 50 mg. three times a day. In all cases a rise of systolic blood pressure varying from 9 to 46 mm. was obtained in five minutes to an hour after administration and the pressure remained up for four hours or more. As far as subjective symptoms were concerned, three patients only felt stronger while the remainder noticed no change. In the acute fall of blood pressure encountered in conditions of shock or after severe hæmorrhage ephedrine might be expected to be of considerable use, but the authors conclude that its beneficial effects are doubtful and that favourable results are only to be expected if it is given early or as a prophylactic. They quote certain opinions to the effect that ephedrine may be definitely harmful to the heart under such circumstances. With regard to the use of the drug in other conditions, a dramatic result was obtained in one case of toxic erythema five minutes after 65 mg. of the drug had been taken by the mouth. In seven cases of urticaria ephedrine was tried, but only doubtful benefit was obtained in two of them, while three patients with angioneurotic œdema failed to react favourably after administration of the drug. More consistent results were observed from the use of ephedrine of asthma in a series of 39 cases. Complete relief was obtained in 56 per cent. and in a further 24 per cent. partial relief. In order to eliminate a purely psychical effect the authors estimated the vital capacity and blood pressure before and after treatment. In one patient, 15 minutes after taking the drug, vital capacity was increased from 20 per cent. of the normal to 33 per cent. and the systolic blood pressure had risen by 20 mm. These objective results corresponded with a marked subjective improvement leading to complete relief from the attack. It is found that undesirable effects, such as nausea and vomiting, are especially likely to occur if adrenalin has previously been employed; some tolerance to the use of the drug was observed in 15 per cent. of cases. With regard to the possibilities of harm from the repeated administration, it is suggested that more observations on the question of renal irritation would be of value since red blood cells and casts were found in the urine of several patients after only a short course of the drug. Observations of this sort are welcome in determining to what extent the therapeutic value of this promising alkaloid is limited by toxic effects.

THE PREVENTION OF PERITONEAL ADHESIONS.

Dr. J. R. Buchbinder,[1] of Chicago, has lately published some experiments upon the prevention of the formation of peritoneal adhesions. His object seems to have been to discover some method by which a tube inserted into the peritoneal cavity could be made to act as a drain for a considerable period. He has succeeded in so far as he has proved that, in normal animals, a serous transudate can be provoked by the intraperitoneal injection of hypertonic dextrose solution, and that if this effusion is voluminous enough fibrin-formation, and so the encapsulation of a rubber drainage-tube, is prevented. In such a way a profuse discharge may be made to exude from a drainage-tube for several days. Further, he has shown that this statement holds good if a chemical or mechanical irritation of the serous coat of the intestine is produced at the time when the tube is inserted. Attention is directed to this experimental work because it illustrates how difficult it is for a research worker to resist the temptation to introduce a modification in the treatment of disease upon the very insufficient grounds of the results of experiments which may not have any relevance at all to the problem concerned. Dr. Buchbinder says "the method opens up possibilities in the prolonged drainage of the peritoneum in cases of diffuse peritonitis." By this he tacitly assumes that the average surgeon would desire to see a profuse flow of serous fluid emerge from his abdominal drainage-tubes inserted for peritonitis, at the expense of the fibrin-forming and thereby infection-localising power of the peritoneum. It is axiomatic that in any infected wound an outward serous flow is desirable and all successful methods of treating acute infections are hyperæmia-producing, lymph flow-promoting procedures. Fomentations, radiant heat, hypertonic salt, the mere opening of an abscess or the incision of a cellulitic area, all have for their object the increase of the flow of lymph or its revived circulation where perhaps stasis already exists. Yet such increased exudation of fluid can be bought too dearly, and in the case of the peritoneum it would seem unwise to adopt, without a much fuller investigation, a method which interferes with that wonderful localising reaction which can only take place if fibrin is allowed to form and glue adjacent viscera to one another in the production of a defensive barrier to the extension of the infection. Moreover, however desirable such profuse flow of serous fluid is, it must ever be remembered that peritonitis is more often than not caused by streptococci, organisms which flourish in the lymph, the serophytes of Sir Almroth Wright. Such organisms can be fought only by the leucocytes which of necessity must have access to them. Tissue culture experiments have shown that the migration of cells cannot take place in a fluid medium alone. Some support is necessary for their movement. This is provided in the body by the network of coagulated lymph which covers the surface of raw or inflamed

[1] Surgery, Gynecology, and Obstetrics, 1927, xlv., 769.

viscera. In the scaffolding of fibrin leucocytes can move; they can reach the infecting organisms which they alone are able to attack. So important is this cellular defence against infection that the use of any agent which directly limits or interferes with fibrin-formation in the infected peritoneum is strongly to be deprecated. Drainage for diffuse peritonitis is always necessary, but the surgeon in instituting it hopes thereby to bring about localisation of the process. He is not likely to do this by interfering with the production of fibrin. The problem of peritoneal adhesions is not the prevention of their formation during an acute infective process, but the elucidation of the cause of their formation, and especially the failure of their resolution in some abdominal affections which have never been acute, and, at any rate at their inception, may not even have been infections at all.

A PORTABLE BASAL METABOLISM APPARATUS.

ESTIMATIONS of basal metabolism may prove of value in determining the relative vital activities of groups of individuals of different races. It has recently been shown that the metabolism of healthy Japanese, Chinese, and American women students living under the same conditions in the same college showed a racial difference, the metabolism of the Japanese and Chinese being perceptibly lower than that of the Americans. Confirmation of this fact has led anthropologists during the past year to develop a project for studying the metabolism of various races in different parts of the world. A stumbling block to such a project, however, is the complicated nature of the apparatus for estimating basal metabolism and its unsuitability for use in regions remote from laboratories. In a recent paper[1] Dr. F. G. Benedict describes his modification of the student respiration apparatus, designed by Benedict and Benedict in 1923, to meet these fresh requirements. The principle of what he calls a "field respiration apparatus" is the introduction of a measured amount of pure oxygen into a closed circuit and the estimation of the time taken for its absorption. This method does away with gas analysis and the need for a gasometer, while it gives an accurate record of the oxygen consumed. The technique is briefly this: the subject breathes through a rubber mouthpiece into a circuit containing oxygen-rich air. This closed circuit consists of a metal can, partly filled with soda lime, to absorb the carbon dioxide given out, and covered with a light rubber bathing cap for the expansion and contraction of air during respiration. The oxygen consumed is replaced from a rubber bag by oxygen saturated with water vapour and delivered in measured quantities into the circuit by a pump of known and constant volume. The experiment begins and ends with the bathing cap at a definite degree of distension, indicated by an index button on the tip of the cap in contact with a fixed point, the oxygen introduced during the experiment being thus equal in amount to the oxygen consumed by the subject. The only major measurement needed for the calculation of the basal metabolism with this apparatus is the time required for the absorption of six pumpfuls of oxygen, normally about ten minutes. Dr. Benedict describes the various parts of the apparatus and the technique of an experiment in detail, and sets out possible sources of error and the means of obviating them. The apparatus, he says, is already being used in Hong-Kong, Jamaica, Peru, Mexico, New Guinea, and South Australia. Those who have used a simple apparatus of this type for estimating basal metabolism cannot fail to be impressed by the ease and simplicity of the process compared with the complicated type in which the analysis of a sample of expired air, followed by calculation, is a prelude to the measurement of the oxygen absorbed.

A TUBERCULOSIS SURVEY AMONG SCHOOL-CHILDREN.

IN the *Journal* of the Norwegian National Association against Tuberculosis for December, 1927, is an account by Prof. Th. Froelich of a tuberculosis survey of school-children started by him in 1912. He wanted to know how many children were already infected by tuberculosis in Oslo at the age of 7, when school begins. To work with as uniform a material as possible he selected the children who had been born between September, 1904, and September, 1905, examining clinically and with the Pirquet test 2900, or 66 per cent., of all the children in Oslo aged 7 years. With the help of the public health authorities his findings were correlated with the notifications of tuberculosis in the town, so that fairly accurate information was available as to the degree of exposure to infection to which each child was subjected. The visiting tuberculosis nurses of the public health service made inquiries at the homes of all the children, and were thus able to follow up the careers till the age of 20 of all except those who left the town before this age. Much of the information obtained in this way is of considerable interest and should help to stimulate the organisation of similar surveys elsewhere. It was found that 84 per cent. of the children were already Pirquet-positive, and that between 4 and 5 per cent. already showed clinical signs of tuberculosis. In 4·8 per cent. there were infectious cases of tuberculosis in the homes. At the end of 1925 75 per cent. of all the children were traced, and of the 1830 children found in 1912 to be Pirquet-positive, as many as 223 (or 12·2 per cent.) had subsequently developed tuberculosis, and 79 had died of it. The deaths from tuberculosis were twice as frequent among the girls as among the boys; for every 1000 boys who were Pirquet-positive at the age of 7 20 died of tuberculosis before the age of 20, whereas for every 1000 girls in the same category there were 39 deaths. The fate of the 332 children who were Pirquet-negative at the age of 7 depended largely on their sex. When the boys and girls were taken together the subsequent incidence of tuberculosis among them was somewhat lower than that among the boys and girls who had been Pirquet-positive at the age of 7. But when the originally Pirquet-negative children were classified according to sex it was found that the subsequent death-rate from tuberculosis among the girls was as high as 5·4 per cent., whereas it was only 0·6 per cent. among the boys. The tuberculosis death-rate among the girls who had been Pirquet-positive at the age of 7 was 3·9 per cent. As was to be expected the tuberculosis incidence was considerably higher among the children in whose homes there were open cases of tuberculosis than in homes free from tuberculosis.

CANCER OF THE UTERUS.

A RECENT report by the Ministry of Health's Departmental Committee on Cancer[1] analysed some 80,000 cases of cancer of the uterus reported from all over the world. Most of them were foreign, and owing to the apparent disinclination of English surgeons in general to publish their results it has been difficult to decide whether the conclusions were applicable to practice in this country. In order to settle this question the Committee has taken advantage of an investigation which Mr. W. McK. H. McCullagh was making at the Samaritan Free Hospital, where high-grade treatment has been given by a number of different surgeons over a suitable period. The facts elicited are described in a further report,[2] and it is satisfactory to find that in nearly 900 cases treated between 1901 and 1920 the results were as good as, or better than, the average deduced from reported cases at home and abroad. The percentage of patients whose

[1] Ministry of Health Report on Public Health and Medical Subjects, No. 40.
[2] Ibid., No. 47. H.M. Stationery Office. 9*d*.

condition was deemed operable was much the same as the average, being 52·8 for cancer of the cervix and 78·8 for cancer of the body of the uterus. The operative mortality for the former condition was, however, only 8·6 as against 17·3, and though for cancer of the body it was higher (11·9) the sample was a small one. Of patients who had abdominal hysterectomy for cancer of the cervix 43·8 per cent. were alive after five years, and 36·6 per cent. after ten. For cancer of the body the percentage of survivors after five years was 61·5. These results, it is pointed out, might be greatly improved, and in cervical cases the successes could probably be almost doubled, if patients would attend for treatment in the early stage of the disease. In the Samaritan Free Hospital series the mean alleged duration of the symptoms was about six months in cases considered still operable; and by this time nearly 50 per cent. of cases are beyond surgical treatment. The time elapsing before patients applied on account of symptoms of cancer of the body of the uterus was found on the average to be about 18 months. Among other conclusions drawn from this report is that in cancer of the cervix younger women are under no disadvantage as regards prognosis, whilst consideration is also devoted to the possible association of cancer of the uterus with miscarriages. "There can be little doubt," it is stated, "of the closer association of miscarriages with cancer of the uterus" than with cancer of the breast, and the suggestion is made that this association should be further studied. As was mentioned in our summary [3] of a circular issued by the Ministry a fortnight ago, it is not the number of children born, but the fact of a birth having taken place, that is of importance in the ætiology of cervical cancer.

The present report, which is the work of Dr. Janet Lane-Claypon and Mr. McCullagh, is a useful appendix to those previously issued. It contains no evidence bearing on the value of radiological treatment, as this was hardly used at the hospital during the time covered by the inquiry.

SOMATIC CHANGES IN MENTAL DISEASE.

THERE are some enthusiasts who tackle light-heartedly the problem of research into somatic conditions in the hope of quickly solving the riddle of the interaction of mind and body and discovering the cause of insanity in bodily changes. How complex are such changes, and how obscure their relation, whether of cause or of effect, to the mental states in psychoses, is well seen in the results of a careful piece of research conducted in Swedish mental hospitals by Dr. Torsten Sonden.[4] The author set out to investigate the supposed correlation between changes in mental state and certain somatic conditions by means of frequently repeated estimations made over long periods in cases of manic-depressive insanity. In each section he gives a full discussion of previous work, exact details of his technique, and experimental and statistical errors; tables and charts are supplied with the values obtained, while a very full account is given of the 11 cases finally selected as suitable for investigation, including diary notes of their mental states throughout the period. It is evident that Dr. Sonden is a worker whose results have been subjected to the strictest controls. He contends that too much research has been directed to the collection of a few results from each of large—and often diverse—groups of cases, and that the more fruitful line of work is that which he has followed, an intensive examination of the range of individual variations in strictly selected small groups; four of his cases were under investigation for 2½ years, and the rest at least for many months covering different phases of mental state. His general conclusion is that some parallelism between mental and bodily states is shown, but only in certain cases; his results give no evidence of any somatic condition which can be considered to cause the mental disorder or throw any light on its causation. He discusses fully the literature on the subject and the theories which have been put forward, and shows that no conclusive evidence exists as to the action of supposed endocrine and autonomic causative factors in the manic-depressive psychosis. The somatic conditions in which he finds some parallelism with the mental state are temperature and pulse-rate, which are often slightly raised in manic periods, and blood pressure, which is raised in manic and melancholic phases alike. Respiratory-rate does not show similar changes. The erythrocyte count, done at two-day intervals, rose regularly in some, but not all, cases at the transition from normality to either mania or depression, and since the serum albumin shows a coincident rise he suggests that the change is due either to an alteration in the fluid quantity of the blood, or, more probably, a redistribution of fluid between blood and tissues. This probability is increased by the great variability of daily leucocyte counts; these tend to be greater during manic periods, especially neutrophils, but so many factors influence such counts that the figures obtained show no clear evidence as to the connexion of these variations with the mental state. Estimations of blood-sugar, non-protein nitrogen, hæmoglobin, urea-nitrogen, and creatinine show no definite parallelism and the experiments on the effect of adrenalin on blood pressure and on the oculo-cardiac reflex and Loewi's reaction give no definite evidence of any special changes of vegetative tonus accompanying the changes of mental phase.

[3] THE LANCET, Jan. 7th, p. 46.

[4] A Study of Somatic Conditions in Manic-Depressive Psychosis. Upsala Läkareförenings Förhandlingar. New series. Vol. xxxiii. Parts 1 and 2. 10 kroner.

THE death is announced of Dr. Alexander Hodgkinson on Jan. 11th at his home at Farnham, Surrey. Dr. Hodgkinson was largely instrumental in founding the Hospital for Consumption and Diseases of the Throat at Manchester, and for many years served on its honorary staff as physician.

THE bicentenary of the birth of John Hunter will be celebrated by the Royal College of Surgeons of England on Feb. 14th. At 4 P.M. Sir Holburt Waring will deliver the Hunterian oration, and at 8 P.M. there will be a dinner at the College. On Feb. 16th a reception is to be held from 3 P.M. onwards at the College and at 5 P.M. Dr. G. C. Peachey will deliver the Thomas Vicary lecture, his subject being the Home of Hunter.

THE next Congress of the Royal Institute of Public Health is to be held in Dublin from August 15th to 20th, at the invitation of the Government of the Irish Free State. The Minister for Local Government and Public Health has accepted the presidency of the Congress, and a list of vice-presidents has been drawn up. It is intended to distribute the work among four sections: (1) State Medicine, dealing with four groups—namely, (*a*) epidemiology, (*b*) municipal, county, and port sanitary work, (*c*) tuberculosis, and (*d*) housing and town planning. (2) Bacteriology, pathology, and biochemistry. (3) Maternity and child welfare and school medical inspection. (4) Production and control of food and milk. The arrangements in Dublin are in the hands of a representative committee, the honorary secretaries being Mr. G. Sherlock (town clerk), Mr. M. Russell (medical officer of health) and Sir William Thompson.

INDEX TO "THE LANCET," VOL. II., 1927.

THE Index and Title-page to Vol. II., 1927, which was completed with the issue of Dec. 31st, is now in preparation. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLIX.

THE TREATMENT OF MINOR DEGREES OF NASAL OBSTRUCTION.

I.* Deflections of the Septum and Abnormalities of the Turbinate Bones.

Since the advent of the operation of submucous resection of the nasal septum there is little doubt that the operation has been much abused, and has been frequently performed when it is quite unnecessary. It must be remembered that a certain amount of septal deviation is the rule rather than the exception amongst the Anglo-Saxon and Hebraic races; it is important then that the practitioner should have some definite guidance as to the question of operation.

The importance of the rôle of infected tonsils and adenoids in the causation of nasal obstruction, especially when associated, as is so often the case, with varying degrees of septal deflection, must be emphasised. Experience in hospital out-patient work has repeatedly shown that the eradication of these septic foci has obviated the necessity for septal operations in many patients sent up as candidates for submucous resection.

Indications for Submucous Resection.

Submucous resection is in present-day surgery almost invariably the operation of choice. Certain cases of *nasal obstruction with marked deflection* obviously require operative interference. Naturally the risk of a subsequent traumatic perforation is great, but provided such perforation be not too far forward the inconvenience is slight, and the perforation may in itself improve the airway. Marked external deformity is, of course, a justifiable indication for operation. In certain cases of *chronic middle-ear catarrh* the straightening of the airway may improve the aeration of the middle ear via the Eustachian tube, or may permit of the introduction of the catheter for purposes of inflation. In deafness due to other causes submucous resection is in my opinion but seldom productive of improvement. An appreciable number of cases of *persistent frontal headache and supra-orbital neuralgia* are due to deviations of the upper part of the septum. The symptoms are probably caused by interference with the ventilation of the fronto-ethmoidal cells, and the straightening of the septum has most satisfactory results. In cases of *hay fever or asthma* where the presence of a septal deviation is aggravating the condition; also in *epistaxis* where the bleeding comes from the summit of the convexity or is due to the collection of dust in the pocket of a deep concavity. Resection of the septum may give most beneficial results in cases of *unilateral atrophic rhinitis* occurring on the roomy side of a nose. Lastly, the operation may be required as a preliminary to the efficient treatment of *nasal polypi*, or of suppuration in the accessory sinuses.

It must not be forgotten, however, that in many cases of nasal obstruction a deflected septum may be merely an accessory after the fact, the real criminal being a chronic rhinitis or a diseased sinus. Here it is obvious that the septum is not to be sentenced until the other offenders have been dealt with.

Collapse of the Alæ Nasi.

Collapse of the alæ nasi is not infrequently the cause of nasal obstruction. Such collapse is almost always associated with the presence of adenoids or of a septal deflection, and the practitioner may well overlook the alar deformity in the presence of the other abnormalities. He is then apt to be disappointed when the symptoms do not disappear after the removal of the adenoids or the anatomically successful straightening of the septum. In the adult, of course, the alar collapse may persist long after the causative adenoids have undergone their customary shrinkage. It is often possible to relieve the condition by means of suitable breathing exercises, thus developing the atrophied dilators of the alæ. The patient should be shown the appropriate movements, and should practise them systematically three or four times daily. At the outset the practice should take place in front of a mirror until the muscles are well under control. If obstruction persist despite the exercises the use of Francis's nasal props may give much relief—these cause but little distress either physically or cosmetically.

Enlargement of the Turbinate Bones.

The other great cause of nasal obstruction to be considered is the enlargement of the turbinate bones. Such enlargement occurs in three stages: (1) Slight general thickening of the mucous membrane. (2) Turgescence. (3) True hypertrophy. These are the pathological changes found in patients suffering from what is popularly designated catarrh.

The first stage is liable to be a sequela of the acute rhinitis associated with the specific fevers, but may also be due to occupational conditions—for example, in stonemasons or tobacco workers, or to injudicious dietetic habits or insufficiency of outdoor exercise. Treatment then consists in the use of the nasal douche—I prefer the use of an all-rubber nasal bulb to the "sniffing" method as less likely to cause headache—or in regulation of the occupation, diet, or exercise of the patient.

Turgescence and true hypertrophy are prone to cause the practitioner to make errors of diagnosis; fully 50 per cent. of the patients sent to out-patient departments labelled "polypi" are in fact suffering from turbinal enlargement. Great disappointment and a certain amount of loss of faith are evinced when no polypus is forthcoming. The naked-eye appearances are admittedly often very similar, and the practitioner would do well to remember that without the use of cocaine and the nasal probe the differential diagnosis may be extremely difficult.

In the turgescent stage the application of cocaine and adrenalin will cause almost complete collapse of the swelling, and it is in such cases that the use of the galvano-cautery is extremely beneficial. It is generally advised that a deep line be made with the cautery point to cause a subsequent fibrosis, but experience shows that relief is often obtained by a light superficial application, which probably has a beneficial action on the vasomotor mechanism. A point to bear in mind is that a very pale and excessive turgescence is found in those addicted to snuff-taking, a practice which is more common than is usually suspected amongst shop assistants, who are debarred from the use of tobacco during working hours. The tumefaction may involve both the anterior and posterior ends of the bone, and in advanced cases partial turbinectomy of one or both ends may be required.

In the third stage there is true hyperplasia, and even after the application of cocaine, which will relieve any coexisting turgescence, the turbinal remains definitely enlarged. Either the middle or the inferior turbinals may be affected, and the treatment will be considered separately.

Hyperplasia of the Middle Turbinal.

In my opinion the cautery should not be applied to the diseased middle turbinal; unpleasant and even dangerous results have followed its use. The main pathological changes are: (*a*) Enlargement of the anterior end. (*b*) Cystic enlargement of the head of the bone. It is well to remember that the pressure of the enlarged turbinal on the septum or its interference with the aeration of the fronto-ethmoidal cells may cause persistent neuralgia across the bridge of the nose or in the infra- or supra-orbital regions.

* Part II., entitled Nasal Polypi and Ethmoidal Disease, will appear next week.

Anosmia and aprosexia are also fairly common symptoms. The best treatment consists in the removal of the enlarged end by the nasal snare, a proceeding which is facilitated if a deep incision behind the enlarged portion be previously made with a punch forceps such as Grunwald's. The same procedure may be used to remove cysts, but if these are friable their complete removal by the snare is often impossible, and a "mopping-up" operation with curette or forceps may be required. Glegg's nasal snare is the best. It has the following advantages: (1) The wire can be easily and rapidly threaded or unthreaded. (2) The size of the loop can be regulated *after* threading. (3) Should more than one application be necessary the loop can be pushed out without twisting.

Hyperplasia of the Inferior Turbinal.

The treatment of the hyperplastic inferior turbinal is also operative, but one must be most conservative as to the amount removed, since marked dryness or even a pseudo-atrophic rhinitis may follow the sacrifice of too great a portion. Removal of the anterior end by the snare will be facilitated if an incision with angular scissors be first made along the attachment of the turbinal to the outer nasal wall, otherwise the snare is apt to slip.

For the removal of the enlarged posterior ends a general anæsthetic is usually advisable, when a finger may be passed into the post-nasal space to guide the loop of the snare into the desired position. The other operations mentioned may be performed under local anæsthesia.

After-treatment.

My usual practice is to instil hydrogen peroxide drops t.d.s. for some three or four days, followed by the use of the nasal wash twice daily until healing is complete. The use of neb. menthol is often soothing and beneficial.

ESTIMATION OF VITAMIN A IN COD-LIVER OIL.

REPORT* ON A COMPARISON BETWEEN THE COLORIMETRIC (ROSENHEIM, DRUMMOND) AND THE BIOLOGICAL METHOD OF DETERMINING VITAMIN A IN COD-LIVER OIL.

THE work summarised in this report was organised by the Accessory Food Factors Committee at the request of Dr. H. H. Dale, Chairman of the Second International Conference (League of Nations) on the Biological Standardisation of Certain Remedies, Geneva, August–September, 1925. A subcommittee of this Conference (Dr. H. H. Dale, England; Prof. Poulsson, Norway; Prof. Voegtlin, United States) had been appointed to arrange for a special test to be made of the validity of the colorimetric method for estimation of vitamin A described by Rosenheim and Drummond [1] in comparison with the biological method.

For the purposes of this test seven samples of cod-liver oil were provided, six by Prof. Poulsson and one by Dr. Dale.

Dr. O. Rosenheim, F.R.S., consented to determine the vitamin A content of these oils by the colorimetric test, and the following four laboratories were invited to make independent tests of the same oils, using the biological method: Department of Biochemistry, University College, Prof. J. C. Drummond; Department of Pharmacology, University of Sheffield, Prof. E. Mellanby, F.R.S.; Department of Physiology, King's College for Women, Prof. V. H. Mottram; Department of Experimental Pathology, Lister Institute, Prof. Sir Charles Martin, F.R.S.

Colorimetric Test for Vitamin A Assay in Cod-liver Oils.

1. *Arsenic Chloride Method.*—The oil is measured from a Wright's capillary pipette, graduated by means of mercury to hold 25 c.mm. and delivering 20 mg. oil, into a test-tube of clear white glass of 10 mm. internal diameter. One c.cm. of the reagent (pure $AsCl_3$) is delivered from a standard 10 c.cm. burette into the test-tube and a reading taken immediately (the time limit one minute) in a Lovibond's colorimeter. The results are expressed in standard units (blue) of the colorimeter. Five consecutive tests made in each case differed on the average by $\pm$ 0·10 unit.

2. *Antimony Chloride Method.*—By means of a standard pipette 2 c.cm. of the oil are measured into a measuring flask of 10 c.cm. capacity. The pipette is rinsed out three times with chloroform, and the solution made up to volume with the same solvent; 0·2 c.cm. (=40 c.mm. oil) of the solution are measured into a test-tube (10 mm. diameter) and mixed with 2 c.cm. of a 30 per cent. antimony chloride solution in chloroform delivered from a standard burette. Readings are taken as above described. Limit of error as above.

The values obtained by the $AsCl_3$ method and its $SbCl_3$ modification agree within the limits of error of each method. The results obtained on the same oils by two independent observers agreed within $\pm$ 0·50 units—i.e., the usual difference in colorimetric work. The figures given in the table below refer to the mean of the values obtained with the arsenic chloride and antimony chloride methods respectively.

Biological Method for Vitamin A Assay.

All the workers raised the question of the exact biological method to be employed, and the Accessory Food Factors Committee was asked to give an opinion on this point.

The method for biological assay of vitamin A (anti-xerophthalmic factor) detailed in the memorandum of July, 1925, drawn up by Prof. Poulsson on behalf of the Permanent Standards Committee of the League of Nations Health Organisation, was discussed at a Conference held at the Lister Institute on Dec. 18th, 1925. The Conference was unanimous in the opinion that the method therein described was defective in that no provision was made for an adequate supply of vitamin D (antirachitic factor) to the experimental animals during the period of the test.

The following general method for the biological estimation of vitamin A in the samples of cod-liver oil was therefore recommended and adopted by the four laboratories undertaking the biological tests:—

1. Young rats of weight 40–50 g., 20–30 days old, to be used.

2. The number of control animals to be equal to that in each group receiving oil.

3. The animals to be fed on artificial diet devoid of fat-soluble vitamin until growth ceases, and excess of antirachitic vitamin (in form of irradiation, irradiated foodstuffs, or irradiated cholesterol) to be supplied during the whole or latter part of this pre-observation period.

4. The material to be tested to be added to the diet when growth has ceased and the weight of the animal has become constant or is beginning to decline.

5. The animals to be observed during a further period of four weeks, during which time the antirachitic vitamin should be supplied.

6. Comparison to be instituted between the doses of the various oils required to restore the same rate of growth.

* Report to the League of Nations Health Organisation by the Accessory Food Factors Committee (appointed jointly by the Lister Institute and the Medical Research Council).

[1] Biochemical Journal, 1925, xix., 753.

7. Not less than three animals to be used for each dose of oil. The oil to be administered separately to each animal. The diluent to be some inert solvent, whose inactivity should be controlled by the behaviour of control animals.

The results obtained by the various workers using the biological method are summarised in the accompanying table. It will be seen, however, that the observers did not in all cases find it possible to institute a comparison on the lines laid down in (6) above, and in two instances comparison was made between the *rate of growth* shown by rats *upon the same dose* of the different oils. By this method quantitative accuracy of comparison is impossible, seeing that the relation between size of dose and rate of growth has not been determined. But the oils can be graded in order of merit provided that the dose selected for making the comparison does not exceed the minimum required for normal growth.

After the results had been submitted, Dr. Dale communicated the results received from Prof. Poulsson (also included in the table), together with the following description of the various oils :—

Oil 1.—An ordinary medicinal cod-liver oil. Details of preparation not available.

Oil 194.—Raw medicinal cod-liver oil prepared by the ancient "rotting" process. The liver remains in open barrels for many weeks, sometimes for several months. This oil is very strongly coloured.

Oils 202, 97, 140, 114.—Ordinary medicinal cod-liver oils, prepared by means of steam. Nos. 97, 140, and 114 have remained in half-filled bottles for two to three years and may have undergone alterations. No. 202 is a fresher oil and has been kept in filled bottles.

Oil 82.—Cod-liver oil prepared in a very primitive way by simply boiling the cod livers in an open pot. Such cod-liver oil is employed by the inhabitants for their own use.

C. = Colorimetric. B. = Biological.

Results.

The grading of the seven oils for vitamin A value by the English workers using the biological test is roughly the same, but there was a marked variation in the values obtained in different laboratories for the same oil. This variation in the results among themselves was at least as great as that existing between the latter and those obtained for the same oils by the colorimetric method. It was not possible to attach numerical values to the results obtained by the biological method. The colorimetric test gave oil No. 1 the first place and placed oil 194 not far behind. Oil No. 1 was also placed in the first rank by one of the two observers who examined it using the biological method. Oil 194 was found next in value in two out of four biological tests; in the other two oil 202 was found superior to oil 194. The results of the colorimetric test and of all four biological tests agreed (1) in consigning an intermediate position to oils 97 and 140, and (2) determining oil 114 to be inferior to these two, and (3) in finding oil 82 to be either very poor in vitamin A or altogether devoid of it.

The Committee finds the biological method does not, at present, permit of sufficient accuracy for the presentation of the above results in numerical form.

Conclusion.

In the examination of cod-liver oils for vitamin A the colorimetric method of Rosenheim and Drummond afforded information consistent with that derived from the biological tests.

In recording this conclusion the Accessory Food Factors Committee, however, considers that before a conclusion is drawn as to the general validity of the colorimetric method for assay of vitamin A, tests should be made with substances containing vitamin A, other than cod-liver oil, such as butter, palm oil, cereal oils, &c.

F. GOWLAND HOPKINS, *Chairman.*
HARRIETTE CHICK, *Secretary.*

September 1st, 1927.

APPENDIX.

Basal diets (deprived of vitamin A) used for the biological tests as carried out in Laboratories 2-5.

Lab. 2 (University of Sheffield, Pharmacological Department).

Caseinogen	400 g.	Lemon juice	140 g.
Rice starch	800 g.	Salt mixture	80 g.
Cane sugar	240 g.	Liquid salt solution—	
Marmite	160 g.	$CaH_4(PO_4)_2$. 176 KI . . 10	160 c.cm.
Olive oil (heated and oxygenated at 120° C. for 12 hours)	160 g.	Water to 2000 c.cm.	
		Water	700 c.cm.

Vitamin D supplied in the latter period of the test by means of 5 mg. irradiated cholesterol administered daily to each rat.

Lab. 3 (King's College for Women, Physiological Department).

Stock diet.	†Certified "A-free" caseinogen	100 g.
	Pure potato starch	320 g.
	Salt mixture	20 g.

To 22 g. stock diet was added 2·5 c.cm. oxygenated cotton-seed oil, 25 c.cm. 5 per cent. solution of marmite, 50 c.cm. distilled water.

Vitamin D supplied during the whole period of the test by administering 2 mg. irradiated cholesterol (suspended in cotton-seed oil) daily, to each rat.

Lab. 4 (University College, London, Biochemical Department).

†Certified "A-free" caseinogen	20 g.	Salt mixture	5 g.
Rice starch	76 g.	Yeast extract (marmite)	5 g.

Vitamin D supplied as 1 mg. irradiated cholesterol dissolved in liquid paraffin administered separately to each rat daily.

† Prepared by Glaxo, Ltd.

Lab. 5 (Lister Institute, Department of Experimental Pathology).

"*F*" *Diet.*

Caseinogen	100 g.	Lemon juice ..	25 g.
Wheat starch	250 g.	Salt mixture ..	25 g.
Hardened cotton-seed oil	75 g.	Water	300 c.cm.
Yeast extract (marmite)	25 g.		

Vitamin D was supplied during the latter part of the test by previously irradiating the cotton-seed oil for 30 minutes at a distance of 33 cm. from the burner of a quartz mercury-vapour arc lamp.

In all cases the caseinogen was purified by heating for 36–72 hours in thin layers at 120° C.

The salt mixtures were all based upon No. 185 of McCollum, Simmonds, and Pitz.[2] In Laboratories 2 and 3 there were also additions of small quantities of sodium fluoride, manganese sulphate, and potassium iodide.

THE RELATIVE CONTENT OF THE FAT-SOLUBLE VITAMINS A AND D

IN A SERIES OF COD-LIVER OILS.

By JOAN LEIGH LEIGH CLARE

AND

KATHARINE MARJORIE SOAMES.

(*From the Department of Experimental Pathology, Lister Institute.*)

THE series of cod-liver oils which form the subject of this investigation was the same as that described in the Report of the Accessory Food Factors Committee on "A Comparison Between the Colorimetric and the Biological Method of Determining Vitamin A in Cod-liver Oil" (see p. 148). The same oils were examined for their content of the antirachitic vitamin D to see whether any parallelism existed between the amounts of vitamins A and D respectively contained in any one oil.

1. *Titration of Vitamin A.*

The method employed was biological and in accordance with the general description given in the Report referred to. The following details may, however, be added :—

Litters of young rats, 3 to 4 weeks old, and weighing between 30 and 40 g., were placed on the basal diet F devoid of fat-soluble vitamins.

Caseinogen	100 g.	Lemon juice	25 g.
Wheat starch	250 g.	Salt mixture* ..	25 g.
Hardened cotton-seed oil	75 g.	Water	300 c.cm.
Yeast Extract (Marmite)	25 g.		

At the end of 14 days the animals were put in separate cages and after a further period of 14 days vitamin D was given in the form of cotton-seed oil irradiated with ultra-violet rays from a mercury-vapour quartz lamp, and incorporated in the diet. The animals were maintained on the diet thus changed until growth had ceased for at least a week or a marked loss of condition or weight had occurred. The oil to be tested was then administered by pipette daily for a month, in doses of 19, 6, and 2 mg., the smaller amounts being diluted with inactivated olive oil. A group of three rats received each dose of oil. The numerical results are given in Table I., and from these was derived the approximate grading given in the table of the preceding Report.

The test on oil No. 1 was carried out in the autumn with young rats which had been born in the late summer and had not, therefore, the same growth capacity as those born earlier in the year. The average weekly increase in weight when receiving an optimum dose (19 mg. daily) of a good cod-liver oil used in this laboratory was only 5·3 g. as compared with 10·2 g. for rats born earlier in the summer.

The degree of accuracy obtainable with the biological method as thus carried out was disappointingly low. There was so great a variation in the behaviour of individual rats treated in exactly the same way that the number in each group would need to be much greater to ensure reasonable accuracy. It is impossible to deprive all animals of vitamin A to exactly the same degree in the preliminary period, and there were great differences in the individual power of response when vitamin A was administered. This was especially so when the doses of cod-liver oil were small. For this reason the results obtained with 2 mg. dose of oil have been omitted from Table I.

The data obtained do not permit a satisfactory comparison to be made *between the doses of the various oils required to restore the same degree of growth*, which is the correct method for quantitative assay of the vitamin. It would be necessary to carry out tests with doses more than three in number and less widely separated. The data given in Table I. do, however, suggest that oils 97 and 194 may be regarded as about three times as potent as oils 114 and 82 respectively although the figures are not, on the whole, consistent enough to permit of more than a rough evaluation. The oils may, however, be roughly graded by the amount of growth made on the 19 mg. doses. On this basis oils 1 and 202 may be taken as equal in value to the standard cod-liver oil; oils 194, 97, and 140 cannot be discriminated, but appear distinctly inferior to the above and superior to oil 114. Oil 82 appears to contain but traces of vitamin A.

TABLE I.—*Assay of Vitamin A.*

Effect of small daily doses of the various oils upon the average weekly weight increments of rats maintained for four weeks on "F" diet (devoid of fat-soluble vitamins) to which vitamin D was added as irradiated cotton-seed oil.

2. *Titration of Antirachitic Vitamin D.*

Vitamin D was assayed by three methods.

METHOD 1.—The vitamin was estimated by the increase in bone calcification occurring after small doses of the various oils had been administered to young rats upon McCollum's (1921) No. 3143 low phosphorus, rickets-producing, diet (wheat 33, maize 33, gelatin 15, wheat gluten 15, $CaCO_3$ 3 and NaCl 1 parts by weight). After three to four weeks upon this diet, if no vitamin-D-containing substance is added young rats invariably develop a degree of rickets which can be recognised histologically, while chemical analysis reveals a very low calcium content in the bones.

Young rats of about 40 g. weight received this diet for 23 days. In one control group of eight rats (negative control group) no cod-liver oil was given. In another control group of eight rats (positive control group) 19 mg. daily of the standard cod-liver oil was given. In 21 other groups containing three rats each the individuals received, respectively, 2, 6, and 19 mg. daily of the seven oils to be tested. After 23 days the rats were killed and estimation made of the ash in the fat-extracted leg-bones (femur, tibia, and fibula) after the method described by Chick, Korenchevsky and Roscoe (1926). The results are given in Table II.

McCollum's No. 3143 diet, however, while deprived of vitamin D, is also deficient in vitamin A and has a defective salt mixture, in that the content of phosphorus (0·30 per cent. P. on the dry weight) is too low both in absolute amount and also in relation to the proportion of calcium contained (1·22 per cent. Ca on the dry weight). It does not, therefore, fulfil the requirement that in the biological assay of a vitamin the basal diet should contain optimal

[2] Journal of Biological Chemistry, 1917, xxix., 341.
* No. 185, McCollum, Simmonds, and Pitz, 1917.

amounts of all essential substances except the one which is the object of study.

As a result of attempts to discover a diet for use in assay of vitamin D, which should fulfil this condition, we came to the conclusion that wheat embryo, first suggested by Miss E. M. Hume, is the best means of supplying vitamin A without furnishing more than a negligible quantity of vitamin D and preferable to hog millet or alfalfa meal, which were investigated by Steenbock, Nelson, and Black (1924).

METHOD 2.—The vitamin D content of the same cod-liver oils was assayed with the use of a diet modelled upon diet F (see above), to which 20 per cent. wheat embryo was added. The proportion of casein-ogen and wheat starch was reduced so as to leave the balance of protein and carbohydrate unchanged. On this basal diet rickets does not usually develop, but the lack of vitamin D can be detected by the lowered ash content in the bones of the experimental animals at the close of the experiment. The test was carried out as follows :—

Young rats about 23 days old weighing 35–40 g. and derived from 14 litters, were arranged in 23 groups with the two sexes and different litters as evenly represented as was possible. Twelve rats in the "negative" control group received no addition to the diet and nine rats in the "positive" control group received 19 mg. daily of the standard cod-liver oil. Each of the 21 other groups contained four rats receiving, respectively, 2, 6, and 19 mg. daily of the seven cod-liver oils. After eight weeks the rats were killed and the ash content of their bones was determined.

TABLE II.—*Antirachitic Vitamin D Content of Cod-liver Oils.*

Average percentage ash in fat-extracted dry bones of young rats receiving various daily doses of the different oils after being maintained for—

Oil No.	23 days on McCollum's 3143 diet. (Method 1.)			55 days on "F" diet containing 20% wheat embryo. (Method 2.)		
	2 mg. dose.	6 mg. dose.	19 mg. dose.	2 mg. dose.	6 mg. dose.	19 mg. dose.
1	31·8*	37·5*	41·2*	57·4	61·1	62·5
194	31·3	35·0	39·3	55·7	57·7	61·2
202	32·3	40·5	40·8	51·6	53·6	62·1

140	31·8	40·9	42·6	54·4	58·3	61·3
114	31·5	34·2	38·6	57·8	58·1	61·0
82	30·8	32·8	38·8	52·1	53·2	61·4
A	..	..	(40·4)	..	..	(6 3·8)
B	(27·1)	..	..	(49·5)	..	..

A = Standard cod-liver oil, "positive" control.
B = No addition of oil to diet, "negative" control.
* Positive control, 44·1 ; negative control, 25·3.

The results obtained with methods 1 and 2 are set out in Table II. In attempting to draw quantitative conclusions, however, the same difficulty arose as was encountered in the assay of vitamin A. The variation in the ash content of bones of rats upon the same ration was frequently as great as that existing between the averages calculated for rats in different groups. Nearly 200 rats were used in the attempt to assay these oils for content of vitamin D, and it is probable that two or three times this number would be necessary to enable any quantitative comparison to be instituted which should possess a reasonable degree of accuracy.

If, however, average ash content of bone be plotted against daily dose of each oil, graphs are obtained from which a rough estimate can be made of the dose which might be assumed to correspond to any definite value of the ash content of bone. This was done with the results obtained by method 2. The value selected was 57 per cent. of the dry weight of the fat-extracted bone, a value about midway between that shown by the "negative" and "positive" control rats respectively. The oils as investigated by method 2 then range themselves as shown in Table IV.

METHOD 3. *Assay of Vitamin D by Increase in Body-weight.*—Steenbock and his collaborators (1923, *a*, *b*) were the first to insist that, as is the case with other vitamins, the presence of the antirachitic vitamin D in the diet was essential for normal growth of the young rat. They have also used increase in weight as a criterion for the detection of vitamin D. The experimental animals must, however, be maintained on a diet otherwise complete and including, of course, an adequate provision of vitamin A. The growth made by the rats used in method 2 has, therefore, been studied with this view and the results are collected in Table III.

Here, again, the variation shown by individual rats in the same group was sometimes found to be as great as that occurring between the averages calculated for the different groups. In the main, however, the results which are summarised in Table IV. may be said to agree with those derived from analysis of the bones.

TABLE III.

Vitamin D in cod-liver oils (method 3). Average weekly increase in weight (in grammes) of young rats maintained for eight weeks on Diet "F" containing 20 per cent. of wheat embryo with supplementary doses of cod-liver oil.

* Positive control rats. Negative control rats, 7·3.

Comparison of Table IV. with Table I. shows that no correlation exists between the vitamin A content and the antirachitic value of this series of cod-liver oils. Oils 82 and 1 are the poorest and best oils respectively as regards both vitamins. Oil 202, however, which was equal to oil No. 1 in vitamin A content, is only equal to oil 82 in antirachitic value, and oil 114, which was definitely inferior to oils 194 and 140 in vitamin A content, is found to be their equal in antirachitic value.

TABLE IV.—*Antirachitic Value of Cod-liver Oils. Criterion.*

Conclusion.

The experiments described in this paper have demonstrated how small is the degree of accuracy which it would seem possible to attain with the biological methods at present available for assay of vitamins A and D, unless a prohibitive number of animals is used. Notwithstanding this drawback the results leave no doubt in our minds that the content of vitamin A in cod-liver oil bears no necessary relationship to that of vitamin D.

This lack of parallelism between the content of these vitamins may be explained, in part, by the fact that vitamin A is less stable than vitamin D and, therefore, more likely to be affected adversely by methods of preparation and storage which involve heat and oxidation. Oil 202, one of the oils poorest in vitamin D, while richest in vitamin A, was also one of the freshest of the oils and had been kept in filled bottles (see report, p. 148).

The medicinal worth of cod-liver oil depends more upon its antirachitic value than upon its content of vitamin A, for the latter is readily and more conveniently obtained from foodstuffs. If the amount of one of these vitamins in a particular oil bears no necessary relationship to the other, as from our experiments we believe to be the case, the biological method of testing cod-liver oil laid down in the United States Pharmacopœia, which aims at the assay of vitamin A only, is open to criticism.

We have much pleasure in thanking Sir Charles Martin and Dr. Harriette Chick for suggesting this research and for the large measure of help and advice given to us by them throughout the experiment, and in thanking also Dr. H. H. Dale, of the National Institute for Medical Research, for supplying the samples of cod-liver oil. We have also to acknowledge our indebtedness to the Medical Research Council for a whole-time grant and to the Lister Institute for the hospitality of its laboratories.

MEDICINE AND THE LAW.

Fishing Vessels and Dangerous Drugs.

THE Dangerous Drugs Act Regulations of 1921 dealt specially with the case of ships not carrying a duly qualified medical practitioner. The Regulations recognised the master of the ship as a person authorised to be in possession of drugs so far as necessary for complying with the requirements of the Merchant Shipping Acts. The master was allowed, subject to conditions prescribed by the Home Office, to administer and supply the drugs to any member of the crew in accordance with instructions prepared or sanctioned by the Board of Trade. In August, 1921, the Home Office granted an authority to skippers of British fishing vessels to be in possession of tinctura chloroformi et morphinæ composita and tinctura opii. That authority has been revoked by the Home Office as from the beginning of the present year. It is replaced by an authority, dated Dec. 30th last, granting the owner of a British steam fishing vessel registered under the Merchant Shipping Acts formal permission to be in possession (for first-aid purposes and for treating injuries to the eye) of a preparation containing cocaine. The preparation consists of cocaine in castor oil with mercuric chloride in the proportion of not more than 1 part in 200 of cocaine and not less than 1 part in 3000 of mercuric chloride. The preparation must be kept under lock and key at the owner's office or place of business; it must be obtained only in quantities sufficient for the vessels concerned, and it must be used for this purpose and no other. Written records must be kept and produced for inspection when required. This new authority by the Home Office has to be read with the Board of Trade notice (No. 90) of August last which prescribed scales of medicines and medical stores for steam fishing vessels absent from the United Kingdom for four days or more. The scales included a first-aid case containing inter alia one ½-ounce bottle of cocaine eye-drops. Under the Dangerous Drugs Regulations the skipper of a fishing vessel to which the Board of Trade scales apply had authority to purchase the necessary supplies of eye-drops. It was found, however, that it is usually the owner or manager who purchases the medical stores, and not the skipper. The recently issued authority is intended to meet this difficulty. "Owner" is defined to mean the registered owner of the vessel or, where a managing owner or manager is appointed, the managing owner or manager.

CANCER OF THE RECTUM.

TREATMENT AND ITS RESULTS.

THE latest report [1] issued by the Ministry of Health is based on the examination of nearly 6000 cases of rectal cancer in which operations for radical cure were performed. The data were collected from ten different countries and the inquiry was conducted by the Departmental Committee on Cancer,[2] which specially acknowledges the assistance given by Dr. F. J. Darbyshire, who examined and abstracted the literature, by the Surgical Statistics Subcommittee, and by Dr. Janet Lane-Claypon and Prof. Major Greenwood. The report covers 70 pages and is a sequel to those on cancer of the breast and uterus [3] which have at various times been summarised in our columns.[4] The principal facts elicited and conclusions reached are as follows.

Operability.

Even now there are no general accepted criteria of operability, each surgeon being guided largely by his personal experience and the type of operation which he practises. Fixation of the rectum, for instance, is regarded by some as the chief contra-indication to operation, the height of the growth being of minor importance, whilst others consider that fixation may be due entirely to inflammatory changes, as is shown, they claim, by the restoration of mobility after colostomy. Information as to operability is given in 5231 of the cases whose records have been examined. When these are grouped under countries of origin the operability varies from 35 to 67 per cent., with a mean for the whole series of 48·5 per cent. It should be remembered that some of the data used in reaching these figures are more than 50 years old.

There seems to be general agreement that the mean operability is higher for women than for men, owing, it is said, to the greater roominess of the female pelvis and its superior resistance to infection. This opinion is borne out by the available information, which is, however, "very limited."

Operative Mortality.

For the purposes of the inquiry deaths have been considered "operative deaths" if they are so described by the author, or (in the absence of any such statement) if they occur within one month of operation. On this basis the operative mortality for 5240 cases of radical operation is shown to be 16·5 per cent. The mortality for 860 males was 18·9 per cent., whilst for 538 females it was only 15·0. The operative mortality (both sexes together) is found to be heaviest (32·0 per cent.) in the case of the combined operation and lightest (15·4 per cent.) in the case of the sacral operation, the perineal operation being intermediate (17·4 per cent.). When the two sexes are considered separately the above order holds good for males, but the lowest operative mortality for females belongs to the perineal rather than the sacral operation.

In view of the difficulties of definition it was decided that growths of the pelvic colon and rectum proper should be considered together. A classification according to position was adopted, the tumours being grouped according to distance from the anal margin. The three groups correspond approximately to anatomical segments of the gut. The first group described as "low," refers to the area lying within 1½ in. of the anal margin—i.e., in general the anu

[1] Ministry of Health: Reports on Public Health and Medical Subjects, No. 46. H.M. Stationery Office. 1*s.* 6*d.* net.
[2] The Committee consists of Sir George Newman (chairman), Mr. C. J. Bond, Sir George Buchanan, Dr. S. Monckton Copeman, F.R.S., Prof. Major Greenwood, Sir Gowland Hopkins, F.R.S., Prof. W. S. Lazarus-Barlow, Dr. J. A. Murray, F.R.S., Dr. T. H. C. Stevenson, Dr. Stanley Wyard, and Lieut.-Colonel A. B. Smallman, M.D. (secretary). Additional members for the Surgical Statistics Subcommittee are Sir Gilbert Barling, Dr. T. Watts Eden, and Mr. E. W. Miles.
[3] Reports on Public Health and Medical Subjects, Nos. 28, 32, 33, 34, and 40.
[4] THE LANCET, 1924, ii., 708; 1926, i., 618; 1926, ii., 184, 611, and 672; and 1927, ii., 288.

and anal canal; the second "middle," refers to that between 1½ in. and 4½ in. of the anus, and therefore takes in the ampulla and anything within reach of the examining finger; whilst the third group, "high," comprises those more than 4½ in. from the anal margin, including the rectosigmoidal junction. These terms refer to the lower margin of the tumour. The following table for 1769 cases shows that the higher the growth the higher the operative mortality:—

Site of Growth.	Total No. of cases.	Percentage at this site.	Died from operation.	Operative mortality.
Low ..	550	31·09	67	12·28
Middle ..	1004	56·76	168	16·79
High ..	215	12·15	55	25·50

Data relating the stage of the disease to the operative mortality are given by one surgeon only, but tend to show that the operative mortality is higher for cases in an advanced stage of the disease. Of the immediate causes of operative death "sepsis" is found to be much the most important, being responsible for nearly half the deaths from operation. "Shock and collapse," the next cause in order of importance, accounts for a little more than half the deaths due to "sepsis."

Fate of Patients Submitted to Radical Operation.

For the purpose of this estimation it was decided to reject all patients who had been operated upon before 1890. Of 2344 other patients about whom the necessary information is available, 39·9 per cent. are estimated as having been alive three years after operation. The percentage varied in different countries from 26·9 to 51·4.

The results of the perineal and sacral operations are found to be practically the same up to the end of the second year, but after that the perineal operation has an advantage over the sacral. Females are found to do much better after the perineal operation than after the sacral. The figures for the combined operation are too small to allow of any definite deductions. The prospects of survival are better for females than for males at all periods after radical operation.

Analysis of 2543 cases submitted to radical operation during the past 50 to 60 years shows that the average number of years lived per patient up to the end of five years after operation was 2·53. On the other hand, it has been estimated that the corresponding figure for the untreated patient is 1·59 years, so that on the average radical operation prolongs the life of a patient by 0·9 year (for patients dying within five years). These figures are less favourable than the reality because they leave out of account the number of years still to be lived by those who survive for more than five years.

Symptoms.

Much the commonest first indications of cancer of the rectum are irregularity of stool, pain (not at stool), and blood in the motions, in the order named. These three signs and symptoms taken together account for 84·5 per cent. of the 1244 cases for which this information is given. Of the later indications of the disease, irregularity of stool, blood in the motions, and pain are found to be the commonest, in the order named, and account for 64·5 per cent. of the 3828 cases for which this information is given.

This clearly shows the great importance of carrying out a thorough examination at the first opportunity of all patients—or, at any rate, of those over 30 years of age—suffering from blood or pain at stool, constipation or diarrhœa, or pain in the anal canal, rectum, perineum, sacrum, or abdomen, in order to detect or exclude the presence of cancer of the rectum. The fact that cancer of the rectum, like cancer at other sites, has no peculiar symptoms or signs, undoubtedly adds to the difficulty of diagnosis, but it does not in any way absolve the patient's medical attendant from the duty of carrying out a thorough examination at the earliest possible moment if any of the chief early indications are present. The statement often made that cancer of the rectum is a painless disease, at any rate in its earlier stages, is in direct opposition to the evidence.

Summary.

In his preface to the report Sir George Newman summarises the principal findings as follows:—

(*a*) On the average a period of 12 months was allowed to elapse between the occurrence of the first symptom of the disease and the patient coming to operation. (*b*) Rather less than half the cases when seen by the surgeons were considered to be operable. (*c*) About a sixth of all the patients who underwent a radical operation died as the result of such operation or from causes connected with it. There is no doubt, however, that it should be possible to secure a considerably lower operative mortality at the present time. (*d*) There is evidence, though limited, to show that the mortality from operation was much higher than the average among those patients who are in an advanced stage of the disease. (*e*) Two out of every five of those submitted to radical operation were alive three years afterwards. He points out that no evidence has been forthcoming to ratify the common belief that rectal cancer is of graver import in young persons than in older ones and draws special attention to the fact that, with the exception of irregularity of the bowels, pain is the commonest first indication.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Austrian Health Statistics.

AT one of the recent sittings of the National Assembly the chief of the Austrian Board of Health gave some interesting facts and figures about insurance and the public health. The number of persons insured against illness under the Working Men's Insurance Act was, he said, over 1,000,000, whilst 200,000 more were covered by the Shop and Trade Assistants Act. The number of the insured members of the civil services was 170,000; the railway servants and officials insured against sickness numbered 150,000, and there were also 180,000 labourers and officials insured in agricultural sick clubs. Altogether, 1,700,000 persons were thus under the control of public *Krankenkassa*, or national insurance. Adding to this figure the number of dependants (members of family who enjoy the benefits of the insurance of the chief of the household) it appears that at least 3,500,000, or 55 per cent., of the total population of this Republic are receiving medical aid under one or other form of insurance and are thus lost to the private practitioner (which explains the constant unsettled condition of the profession). The annual expenditure on this welfare care amounts to about £6,000,000 for the labourers, and nearly £3,000,000 for the trade assistants, employers and employed contributing in equal proportions.

Last year proved fairly free from serious epidemics of contagious or transmissible diseases, and no case or cholera, typhus, or small-pox has been imported into this country; diphtheria has rather increased (from 3755 cases in 1926 to 5051 in 1927), and so has scarlet fever, but both have taken for the most part a rather mild course. The number of typhoid cases is constantly decreasing, and the hope is justified that with improvement of the water-supply it will diminish still further. Trachoma is endemic in the south-eastern province of Austria, which has been taken over from Hungary, and the progress of public health in this region is very slow and difficult, owing to the low standard of living of the population. The number of cases of acute poliomyelitis, which was rife last year in the Balkans and also in Central Europe, has fortunately not risen above 130, so that there is and was no need for anxiety. As regards venereal diseases, the figures of the hospitals show a constant decline. In 1925, the total number of patients treated in the State hospitals for venereal

diseases was 6246 for syphilis and 6028 other sexual diseases, whereas in 1926 the numbers were 5706 syphilitic and 5747 other cases. Incidentally, it may be mentioned that in 1925 the number of prostitutes controlled by the police in Vienna was 1097, and in 1926 only 1014. A considerable increase in the consumption of alcoholic beverages has been noted in the past year, especially of heavy beer and cognac. The reports of the Ministry of Agriculture and the Customs Board also show that large quantities of heavy wines have been imported, and the police officers have dealt with over 16,000 persons found drunk in Vienna alone, of whom over 2 per cent. were juveniles.

The war has left us a sad inheritance; there are 53,259 war invalids besides 31,864 war widows, 69,593 orphans, and 24,192 dependants of men who died in action or from war diseases. All these persons are receiving pensions.

Tetanus.

Dr. O. Hock has recently published a short paper on work done in the accident ward of the first surgical clinic of the University of Vienna, which is directed by Prof. Eiselsberg. He deals chiefly with the cases of tetanus, of which only 25 have been observed during the last 20 years. Nine of these proved fatal, four of the patients being admitted with fulminating signs of the disease, and dying from 24–56 hours after the first symptoms developed. In all these cases there had been very extensive destruction of the soft tissues after severe injuries, and post-mortem no other lesion was found except a hyperæmic condition of the brain. In the other five cases, however, pneumonic and cardiac changes were observed. All the patients, with one exception (in which only the masseteric muscles were affected), suffered from severe general tetanus with trismus, opisthotonus, and spasms of the diaphragm and other muscles. The treatment given always includes injections of at least 100 units of tetanus antitoxin daily, given by subcutaneous, intravenous, or intraspinal injection, followed by chloral hydrate per rectum. Injections of morphia or pantopon are given freely, and novocaine is injected into the masseters if trismus is present. Absolute rest in a dark room is required. Every patient with an injury suggestive of tetanus receives an injection of 20 units of antitoxin as a prophylactic measure; this is sufficient either to prevent the disease from developing or to make its course very mild. This prophylactic dose was employed in 1300 out of 4655 cases of accident treated last year, and tetanus developed in only four of them. The sole drawback to its use is a disagreeable itching, occurring in some cases a few days after the injection together with a serum rash.

Diagnosis and Prognosis of Syphilis of the Aorta.

The problem presented by aortic syphilis in large cities was discussed by Prof. H. Schlesinger at a meeting of the Vienna Medical Society a short time ago. It is a mistake, he said, to judge of the influence and frequency of syphilis from the figures obtained in the post-mortem rooms for these are very misleading and give only the minimal figure. In a series of necropsies in Germany, for instance, undoubted syphilitic changes were found in only 2·5 to 5·5 per cent. of the bodies, whereas clinical investigation of large numbers of patients proved that in the later age-periods from 10 to 15 per cent. had been infected. Prof. Schlesinger finds that 14 per cent. of the patients in his wards have syphilis, the males being more often affected than the females, and he thinks that 10 per cent. of the Vienna population suffers from the disease in a recent or chronic form. The Wassermann reaction, he says, only gives a positive answer in 75 per cent. of cases and a negative result does not denote absence of infection. Of late years cutaneous manifestations have been much less common and the organism more often affects the central nervous system and the circulation. Intensive treatment seems to be responsible for the change; it diminishes the interval between infection and the manifestation of aortic disease, and in the last 20 years statistics of necropsies show a rapid increase of aortitis, which is now by far the most common form of luetic disease of the internal organs. Diagnosis is generally easy, unless severe atheroma is also present; prognosis is better than is usually supposed, especially in aortitis supracoronaria, and sometimes the condition is actually benign especially when it is accompanied by neurosyphilis. Many patients have hardly any symptoms for years, but the condition is always dangerous, as over half the affected persons ultimately die from the effects of the aortic changes. Antiluetic treatment improves the prognosis slightly, and good effects are seen in aortalgia, and in stenocardia; aortic aneurysm is often well controlled for a long while. Mild treatment, said Prof. Schlesinger, is better than intensive, and not more than 3·5 g. of neosalvarsan should be given in the course of treatment. Failing cure, it is often possible to ensure quiescence of the pathological processes in the blood-vessels.

Public Health Services.

COÖRDINATION OF THE PUBLIC HEALTH SERVICES.

In the counties of Essex, Hampshire, Gloucester, and West Sussex an assistant of the county medical officer acts also as medical officer of health for one or more local sanitary areas in the county. Dr. James Pearse has investigated for the Ministry of Health how this arrangement is working, and has come to the following conclusions[1]: 1. The local authorities within the districts investigated have almost unanimously expressed their satisfaction with the scheme, and approval has been especially marked from authorities zealous in public health activity. 2. In no district have difficulties been experienced from the dual relationship of the medical officer to the district councils and the county council. Some authorities have expressed the view that there is advantage in the liaison effected. 3. The making of a combined appointment reduces the number of officials working in a given area, increases the opportunities for efficient work in each of the appointments combined, and reduces the difficulty sometimes met by members of the general public who may need official assistance, but may not know where to find it. 4. An officer holding a combined appointment has the advantage of a wider outlook and larger range of official interests, and in particular the independence proper to a medical officer of health relieves in this respect the monotony and the less responsible work of the assistant to a county medical officer. 5. The public health services must benefit by improvement of the opportunities thus offered to new recruits. 6. The definite advantages of the system are such as to merit its continued encouragement, and the taking of such steps as may be necessary to prepare for its further and more uniform development.

THE REGISTRAR-GENERAL'S WEEKLY RETURN.

We have made a practice of calling attention to this useful publication for some time past at the beginning of every year. The first Weekly Return for 1928 does not contain any startling innovations of type or arrangement, but it does include on p. 3 a new and useful feature in the table of comparative death-rates in the eight largest towns for each of the four weeks previous to publication. A further useful addition is the inclusion in Table 5 of the number of live births and of stillbirths occurring in London during each week of the preceding quarter; this table, too, with

[1] Report No. 45 on Public Health and Medical Subjects. H.M. Stationery Office. 1928. 6*d*.

a little compression now allows room for two columns, one of which gives the total cases and total deaths from important infectious diseases during the year as far as it is already completed, with the corresponding figures for last year. The Weekly Return is, of course, supplied to sanitary authorities and their medical staff, but there must be many practitioners who would find it useful to keep it at hand for reference, if only for the reason that their lay friends are making increasing use of the information which it contains. The price is 6*d*. net per issue, from H.M. Stationery Office.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 7TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 275 (last week 247); scarlet fever, 1715; diphtheria, 1376; enteric fever, 53; pneumonia, 2252; puerperal fever, 44; puerperal pyrexia, 104; cerebro-spinal fever, 12; acute poliomyelitis, 8; acute polio-encephalitis, 2; encephalitis lethargica, 31, dysentery, 10; ophthalmia neonatorum, 98. There was no case of cholera, plague, or typhus fever notified during the week.

The cases of small-pox were notified from 16 counties—viz., Berks 1 (Reading), Derby 11, Durham 35, Isle of Ely 5 (North Witchford R.D.), Lancaster 33, Lincoln, parts of Lindsey 3, Northumberland 11, Nottingham 15, Stafford 3 (Stoke-on-Trent), Sussex West 13 (East Preston R.D.), Warwick 10, Yorks N. Riding 14, W. Riding 43, Brecknock 8, Glamorgan 15, Monmouth 55.

In Sussex the original source of infection is stated to have been the East Preston Poor-law Institution (in which union Worthing is situated), which has been closed in consequence. It is not known where the man who introduced the infection into the county contracted the disease, but at least one other case has been notified in another part of the county. This was one of three casuals who went to Horsham from Brighton and entered the Steyning Poor-law Institution at Shoreham. Here there were 13 casuals, 7 of whom were vaccinated; the other 6 (including the 2 from Brighton) refused to be vaccinated, and these 2 who have been detained also refused to have their clothes disinfected. The men have been isolated and the casual ward closed. Local authorities in Sussex are actively coöperating in preventive measures.

Since then a case of small-pox has been reported from the Edmonton Poor-law Institution.

Deaths.—In the aggregate of great towns, including London, there was one death from small-pox, 5 (2) from enteric fever, 107 (44) from measles, 4 (1) from scarlet fever, 32 (8) from whooping-cough, 68 (18) from diphtheria, 61 (8) from diarrhœa and enteritis under two years, and 155 (30) from influenza. The figures in parentheses are those for London itself. Of the 63 fatal cases of measles outside London 14 were reported from Bristol, 5 from Derby, 14 from Manchester, 3 each from Salford and Plymouth, while the figures from Glasgow and Dublin for the same week were 40 and 18 respectively. The deaths from enteric fever outside London occurred in Reading, Norwich, and Chester, one each. The death from small-pox occurred in a poor-law institution just outside the Bradford county borough boundary. The number of stillbirths registered during the week was 277 in the great towns, including 46 in London.

BRIGHTON HOSPITALS AND RATES.—The revaluation of the borough is viewed with considerable alarm by the governors of the hospitals in Brighton. These institutions have hitherto been rated at a purely nominal figure, but now under the revaluation scheme startling increases have been proposed. The assessment of the Sussex County Hospital—the largest in the town—is to be increased from £64 to £3375, a rise of 5000 per cent., and other hospitals are similarly affected. It is not yet clear how the situation will be met. The Brighton figures have been forwarded to the Government Central Valuation Committee, a body which is collecting information about the practices hitherto adopted in various areas in regard to the assessing of hospitals and kindred institutions.

"Audi alteram partem."

COMMISSIONS IN THE R.A.M.C.

To the Editor of THE LANCET.

SIR,—Major W. E. Home called attention in your last issue to the fact that the list of applications for commissions in the R.A.M.C. closes on Jan. 20th. Although the primary object of the Medical Service is to furnish the army with medical officers for carrying out the various duties in connexion with it, yet, after the South African War, chiefly through the energetic influence of Sir Alfred Keogh, a further and special duty for the education and training of the entrant was thrown upon the Medical Service, and the R.A.M.C. was established. That addition, involving a great change, would not have proved beneficial had it not been attended with facilities for keeping abreast of the work done in medical science in civil life and for carrying on a constant and never-ceasing inquiry into conditions and disease that either are not or are but ill-understood. In the R.A.M.C. that has been attained. I observe some signs that that standard will not, in future, be maintained owing to the reduction in the personnel to a number that is uneconomic, and to the pressure of political circumstances the moment it is realised the educational organisation might be abolished. And unless the service as it is attracts the good if not the best men turned out of the medical schools there will be no excuse for the maintenance of the present educational organisation the like of which there is none.

Indeed, the organisation is magnificent, but the scope for employment after the training is far too narrow, with the result that stagnation occurs. The initial training is unique; the opportunities for seeking new knowledge, for gaining incomparable experience in diverse directions, for leisure to deliberate over work done and that to be done are almost beyond the conception and belief of the medical student. Would-be entrants are, however, few, and there is no competition for places.

This result seemed to me, a few years ago, inevitable. It may well be asked who is there better fitted for hospital appointments, for the public health services, for many other than strict medical duties under several Government departments overseas as a well-trained officer of tne R.A.M.C.? Yet, for the trained there are but few channels at present open for him to enter in which there is a prospect of employment of a permanent nature. There are indeed openings in many directions beyond the services for the army in times of peace for which the R.A.M.C. officer is eminently suited and qualified; and it is even now a great loss to the State that his services are not in demand, and early in his career.

I am convinced more extensive use should be made of the great and valuable educational organisation built in relation to the R.A.M.C. than is possible under present conditions. Unless this organisation can be fully utilised I fear that before long the cry for economy will affect it. Scrapping would be calamitous and end in the destruction of an instrument by means of which all medical officers for State services should be trained as a condition of entry for permanent employment under usual conditions. The State needs this additional organisation attached to the R.A.M.C., so that the doctors who desire to enter any of the State services shall have opportunities to fit them for the work that would fall to their lot at home as well as overseas.

The greatest attraction of all would, I believe, be a prospect of permanent employment which none but the State can find, organise, and utilise to advantage.

I am, Sir, yours faithfully,

JOSEPH GRIFFITHS,
Colonel, R.A.M.C.

Cambridge, Jan. 14th, 1928.

THE PRESENT POSITION OF THE VOLUNTARY HOSPITAL.

To the Editor of THE LANCET.

SIR,—In reply to the numerous critics who have written in opposition to the views expressed in my address which you published on Dec. 17th, 1927, I would point out that the thesis which I was supporting was that the voluntary system of management of hospitals, because of its present well-established position and success, was preferable to any other system of management. I would emphasise the word "management," because I consider that is the keynote of the whole question; how large a measure of their funds is derived from voluntary contributions is of less importance, as long as their management remains voluntary.

In answer to Prof. Berry, I would point out to him that my statement to which he objects, that the alternative to the voluntary system of management is bureaucratic control, is in fact correct. For our country that is the precise alternative which is being actively pressed at the present moment. The support of the voluntary system is for this reason of paramount importance, as constituting the only competing system actually in being, and exhibiting sufficient strength (I believe) ultimately to prevail against that formidable bureaucratic menace. Prof. Berry is really upon my side, for he and I both find bureaucratic control "detestable." We differ only in the measures which should be adopted to prevent the extension of that "detestable" control in this country. Like Prof. Berry, I have some first-hand knowledge of American and Canadian hospitals, but my knowledge is not so recent as his. The one instance of somewhat superfluous antisepsis which I quoted was vouched for by a famous Canadian surgeon who named the hospital and obviously described what he had seen. But I readily admit that this instance could not be now regarded as typical of American hospitals.

Those of my critics who make it a reproach to the voluntary hospitals that "they cannot deal with more than 20 per cent. of the work which comes to them" do not seem to realise that the congestion which explains such a position is largely due to the enormously increased popularity, as compared with other institutions, of the voluntary hospitals; they have long waiting-lists, while there are hundreds of permanently empty beds in the poor-law infirmaries. The attitude of these critics reminds me of an incident which others will recall as well as myself. In 1913 the Senate of the University of London invited Prof. Delbruck, of Berlin, to give two lectures in London upon military history. At the conclusion of the second lecture the then Vice-Chancellor invited the lecturer and some half-dozen members of the Senate, of whom I was one, to an impromptu dinner at a club. In the course of after-dinner conversation Delbruck commented with extreme bitterness upon the relative prosperity of the British, as compared with the German, colonies in Africa, and he ascribed the inferiority of the latter to the poorness of the territory which Germany had acquired as compared with England. The German colonies, he said, were relatively empty of colonists. I ventured to suggest, speaking from personal experience, that this was perhaps due to the fact that even Germans did not always like autocratic German rule, and that I myself knew many Germans who had migrated from German South-West Africa to British South Africa to settle there. The remark produced an explosion of wrath from Delbruck. Thumping the table with his fist he said, "I know that, but it is for the good of the Fatherland that Germans remain in German territory and they *shall* like it." We remain a relatively free country, not yet entirely at the mercy of our bureaucrats, and at present there is no means of compelling patients to enter poor-law hospitals when they prefer to wait their turn for admission at the voluntary hospitals. The remedy surely would be to provide more accommodation at the hospitals where admission is eagerly desired than to seek to enlarge the accommodation at hospitals in which there are already vast numbers of empty beds which cannot be filled.

The only specific accusation in Mr. Mort's letter which seems to call for reply is that I have "described a condition in a small area of London and from that erroneously generalised for the whole of the country." My address, however, in its opening paragraphs, gave chapter and verse for the conclusions which two Parliamentary committees, after taking much evidence deliberately formulated—viz., "that the voluntary system should be maintained." I invite Mr. Mort to refer to my paper again and to look up the references I gave there of the evidence in support of that thesis, which was also mine, evidence derived from all over the British Isles.

I remain an impenitent believer in the value of tradition and experience. I will say without hesitation that I am convinced there *is* a larger measure of "humanity and the spirit of service" to be found in the average voluntary hospital than in the average poor-law institution. Again, if I understand aright an obscurely worded question addressed to me by Mr. Mort, I would answer that if I had appendicitis myself, I would rather be operated upon, let us say, in St. Bartholomew's—the oldest of the voluntary hospitals—than, let us say, in the North Middlesex Hospital. That prejudice would, I think, be shared by many. Perhaps Mr. Mort might read with profit, and a certain chastening, the tragic story of an operation for appendicitis in Sir Frederick Treves's book, "The Elephant Man."

Dr. Watson makes a suggestion of "a combination between the poor-law and general hospitals." This is, in fact, partly embodied in a scheme sketched by Mr. Walter Spencer and myself in two articles that appeared in the *Times* of Jan. 10th and 11th upon which the editor of that paper in a leading article makes the comment "such a scheme seems to be peculiarly well suited to the existing state of affairs in the hospital world." The same leading article has the following summing up in support of the thesis I have been maintaining: "The voluntary hospitals have reached their present condition of efficiency as a result of prolonged effort and by way of countless trials and stresses. Most of them are the product of centuries of evolution. They embody great traditions and possess stores of experience of which all those who serve them become the inheritors. These traditions and this experience are treasures of inestimable worth. . . . Such a hospital service as this country possesses could not be reproduced by any conceivable effort of public authorities or expenditure of public money."—I am, Sir, yours faithfully,

E. GRAHAM LITTLE.

Wimpole-street, W., Jan. 14th, 1928.

NOMENCLATURE OF DISEASE.

To the Editor of THE LANCET.

SIR,—In an annotation in your issue of Dec. 24th, 1927 (p. 1355) an important suggestion appears to the effect that an attempt should be made by an authoritative committee to define names of disease and other medical terms in everyday use. I advocated this several years ago when writing of "tuberculous pus," after an inquiry from various authorities had revealed a widely differing conception as to what was meant by the word "pus." Like sciatica, rheumatism, and many other terms "pus" is a word hallowed by time, dating from a period when pathological conceptions were inexact, and for that reason its meaning still remains inexact. It should not be difficult to form such a nomenclature committee, not from one medical body, but from those mainly concerned, on the lines perhaps of the Joint Tuberculosis Council and similar organisations. It only needs someone to take the initiative. I am, Sir, yours faithfully,

Paignton, Jan. 5th, 1928. E. WARD.

GASTRO-DUODENAL ULCERATION.

To the Editor of THE LANCET.

SIR,—The letters of Dr. Ryle and of Drs. Izod Bennett and Moncrieff in your issue of Jan. 14th afford a welcome confirmation of the valuable effects of intensive alkaline treatment. These authorities, however, seem to have mistaken to some extent the purpose and scope of our article. Alkalis and basic products have been used at some time or other by several generations of medical men and often in intense doses. Since Kussmaul and Fleixner in 1893 introduced the use of large doses of bismuth compounds amounting to 20 g. or more per day, the literature contains many claims as to the efficacy of this treatment. The method is still successfully used on the continent, and, in our opinion, the good results undoubtedly obtained in many cases depend on the action of the massive dose of bismuth on the gastric secretion. In America Sippy's excellent work further extended this use of basic substances, but no single man can claim to have introduced the method. For years past the use of large doses of alkali has been so definitely recognised as a general principle by many experts on gastric work that we felt that the time to point this out was long past. Our article in no way claimed any originality for the use of alkali in large or small doses for the treatment of stomach diseases. Such a claim at this time of day would be absurd. We do claim to have presented some definite evidence that the *majority of uncomplicated gastric and duodenal ulcers can be treated successfully by giving sufficient alkali to control the injurious effects of the gastric secretion.* This is not generally known, at least in this country. The article was meant for the general practitioner and not for the expert. Its purpose was to help the medical man who is often sorely perplexed to know what to do in these cases.

Dr. Ryle objects to the "assumption" that the ulcer is "cured." Well, we need not quarrel about terms. If a patient who has suffered agonies for several years obtains complete relief which lasts for four or five years, and perhaps indefinitely, and if at the same time radiograms show that his ulcer had healed and still remains healed, then may we not term the result a cure? One of us was unfortunate enough to suffer from a duodenal ulcer from 1908 to 1914. Diet and other methods of treatment proved unsatisfactory and the condition became almost unbearable. In 1914 the use of excessive doses of sodium bicarbonate and bismuth carbonate taken for several weeks gave entire relief from symptoms. This good result has continued, and with the exception of a few comparatively mild attacks of discomfort during 1915, which were quickly relieved by alkali, no symptoms of any importance have been present since that time. Are we not justified in calling this a cure? It is generally acknowledged that there is a special tendency or "diathesis" in the constitution of the subject who develops gastric ulceration, but our experience points to the conclusion that the judicious and timely use of alkali in sufficient dosage will prevent recurrences in the majority of patients. If an ulcer of the leg disappears may we not say that it is *cured* even if at some future time an ulcer appears on the other leg? We do not say that alkali will cure the *tendency* to gastric ulceration. We think that we are justified in claiming that many stomach ulcers are cured, but we do not wish in any way to press the point as long as our meaning is clearly understood.

The second "assumption" to which Dr. Ryle objects is our statement that the effects of the treatment are to be attributed to the alkali. We have tried the usual dietetic and other methods of treatment, and in our hands the results obtained are not to be compared with those following the use of alkali. Though the point is difficult, or perhaps impossible, to prove, yet all the available evidence points to the use of alkali as the most effective means at our disposal for the healing of ulcers. Many patients who had been receiving various kinds of treatment for years without much success have yielded to the intensive alkaline method in a few weeks. Dr. Ryle's statement on pyloric stenosis is not in accord with our experience.

Another "assumption" we have made is to the effect that acidity can be easily controlled by alkali in the majority of cases. On this point we possess ample evidence which we hope to publish later. We do not claim that it is always easy to control acidity, but that it is by no means difficult to do so to a sufficient extent in the average patient. Dr. Ryle thinks it important that in matters of this kind our conclusions should be based on sound and well-weighed evidence. We claim that our evidence is both sound and well weighed. Our conclusions are based on our experimental results and we have taken the greatest care to ensure that these results are reliable. We agree that results and findings may sometimes be difficult to interpret, and in such cases we are reduced to formulating what appears to be the most probable explanation. We do not really feel that Dr. Ryle's friendly criticism has any bearing on our statements.

With regard to the remarks of Drs. Bennett and Moncrieff we agree that there is ample evidence in the literature that ulcers are sometimes healed under all sorts of treatment—sometimes, indeed, in spite of treatment. There is little doubt that many patients must be the victims of acute ulceration without experiencing any symptoms whatever, and it is equally certain that these acute ulcers tend to heal very rapidly. We also agree as to the importance of attending to septic foci, such as infected teeth, but unless we are misinformed with regard to the general attitude of the profession on this subject there is at present little risk of the teeth, septic or otherwise, being overlooked. No doubt judicious spacing of diet is useful, and, while no one doubts that much can be done by diet, the present unsatisfactory position of the treatment of ulcer proves that something more is required.

As already stated, the main purpose of our article was to help the general practitioner, and to point out that by means of an exceedingly simple method he can treat with success the great majority of the usual cases of gastric and duodenal ulcer. The chief part of the article contains the evidence for this claim and was presented in the radiograms. The comparatively short text was given to explain the reason for the treatment and was meant as a simple practical exposition of a successful method. In such an article, which must not be considered as a general scientific discussion of the subject, no references are required. In a future article we hope to deal with the subject more fully when all the pertinent references will be given.

Finally, we would emphasise the statement made in our paper that the method has been in use by us for about five years, and that it was only after an experience extending over this period that we thought it advisable to make it more widely known. We possess radiograms showing quite definitely that patients treated four or five years ago still show no evidence whatever of any return of the ulceration. In the face of the very definite statement to this effect made in our paper it is misleading to say that our experience only extends over a year or so. Our experience goes back for over ten years in the case of a few patients, and for four to five years in the case of a fairly large number of patients.

We would like to point out that it may be advisable in some patients to give the alkali three times a day for several months after the ulcer symptoms have passed over; also, after an operation for ulcer, it is, in our opinion, advisable to give some alkaline treatment for a considerable time.

We are, Sir, yours faithfully,

HUGH MACLEAN,
ISAAC JONES,
GEOFFREY FILDES.

St. Thomas's Hospital, S.E.,
Jan. 17th, 1928.

HYDNOCARPATES AND IODIDES IN LEPROSY.

To the Editor of THE LANCET.

SIR,—I have read with great interest Sir Leonard Rogers's article on the curative action of hydnocarpates and iodides in leprosy, published in your issue of Jan. 14th. The fact that, according to Sir Leonard Rogers, alepol has no irritating effect on the veins certainly gives it an advantage over other preparations. However, it is impossible to assert its superiority in therapeutic action, as its discovery is so recent that no definite statistics can be obtained until tests covering a considerable number of years have been made. In my opinion the lepricide action of sodium hydnocarpate is of little value. Many preparations such as turpentine, salicylate, antimony, &c., if administered in adequate quantities at the vital moment produce entirely similar reactions. I consider the use of iodides to be extremely dangerous and have myself seen a patient apparently cured relapse under their action.

In his Croonian lectures of 1924 Sir Leonard Rogers declared with similar enthusiasm that chaulmoogra oils and its derivatives would cause the total elimination of leprosy from the earth in a relatively short time. Many leprologists who expected great things on the strength of this statement were so disappointed by the results obtained that they have ended by mistrusting this method of treating leprosy. Notwithstanding the undoubted advances that have been made in the treatment of this deceptive disease during the last ten years, my experience has led me to the conclusion that there is no remedy entitled to be called "specific." I believe that the future treatment lies in the use of specific vaccines which unfortunately cannot at present be prepared from artificial cultures.

I am, Sir, yours faithfully,

JAMES HASSON, M.D.

Cleveland-square, W., Jan. 14th, 1928.

GONORRHŒAL URETHRITIS IN MALE CHILDREN.

To the Editor of THE LANCET.

SIR,—Writing in THE LANCET of Sept. 24th, 1927, Mr. B. Buckley Sharp finds that this condition is of rare occurrence. Here in Bombay, unfortunately, it is fairly common, and during my experience of two years at the J. J. Hospital, Bombay, I have seen about 30 cases of gonorrhœal urethritis in boys under 12. I agree that it is only on rare occasions that infection spreads beyond the anterior urethra, but I have seen a boy aged 8½ who had gonorrhœal arthritis with the prostate and vesicles definitely enlarged and tender. In another case, a boy aged 11, there was marked left epididymitis which subsided under appropriate treatment within eight days.

I am, Sir, yours faithfully,

K. TURNER,

Hon. Assistant Surgeon (Venereal Department),

Dec. 27th, 1927. J. J. Hospital, Bombay.

FACIAL LUPUS.

To the Editor of THE LANCET.

SIR,—In your issue of Nov. 26th, 1927 (p. 1118), appeared a very interesting account of light treatment in the London Hospital by Dr. Sequeira and Dr. O'Donovan. In their experience one type of facial lupus has proved extremely resistant to treatment. In their own words: "The most unfavourable type is that in which there is great thickening of the whole skin. When the face is involved the lips and cheeks become bloated and purplish-red in colour with a form of lymphatic infiltration resembling a pseudo-elephantiasis. Such cases are not common, but I have followed several from their early stages and have found nothing influence them." And "there is also a small percentage of cases that we cannot influence, particularly what may be called the 'facial lymphatic' type. Light baths have little or no effect." One such case has recently been treated at Leysin by Dr. A. Rollier, and I feel it may be of interest to mention that definite improvement was obtained by general sun and air cure. The case was recently presented to the Royal Society of Medicine by Dr. H. C. Semon, who has contributed an account of it, with illustrative photographs, to the Society's *Proceedings* (1927, xxi., 185).

I am, Sir, yours faithfully,

Leysin, Dec. 1st, 1927. T. W. T. DILLON.

NERVOUS INSTABILITY AND THE INTAKE OF SUGAR.

To the Editor of THE LANCET.

SIR,—May I suggest that the relationship between sugar consumption and many of those various nervous states grouped somewhat loosely as "neurasthenic" would warrant careful investigation? I believe it to be true that the consumption of sugar per head has increased by roughly twenty times during the last 60 years. Cases of nervous instability become more prevalent. That some endocrine disturbance occurs in many is a growing conviction. It seems possible that excessive intake of sugar is largely responsible for such disorder. To obtain proof from feeding experiments upon animals is difficult, because subjective symptoms similar to the early hypersensitive manifestations which occur in civilised man are not easy to follow in animals. Conclusions drawn from clinical observations may have far-reaching results. I am, Sir, yours faithfully,

London, Jan. 9th, 1928. MACPHERSON LAWRIE.

AN OPERATION FOR THE ALLEVIATION OF DEAFNESS.

To the Editor of THE LANCET.

SIR,—I have read with interest the account given by Major Nesfield of his operation in your issue of Dec. 24th, 1927, as well as the ensuing correspondence, a part of which seems to deal rather with a wish to prevent possible infringement of copyright of another operation designed for a different purpose. Dr. William Hill strikes a necessary warning note as to the failure of former suggestions, and rightly stresses the necessity for careful investigation of results of the new method. It should, however, be borne in mind that, because earlier operations have failed in their object, there is no reason why later ones, carefully designed, should not be successful. The idea of the Nesfield method seems to be based upon rational lines, but there would appear to be a possible danger of its practice falling into inexperienced hands and faulty technique and after-treatment resulting in failure and possible disaster from suppuration or other untoward results. Another danger lies in the possible indiscriminate application of the method and its employment in cases where other and less drastic treatment would suffice. It is only fair to note that Major Nesfield, in his reply to criticism, issues a warning against this latter danger. I call to mind, however, a case which came into my hands some 12 or 13 years ago. It was suggested by a competent otologist to a lady suffering with a blocked Eustachian tube on one side that she should submit to a mastoid operation for the purpose of dilating the tube from the tympanum because it was impossible to introduce a Eustachian catheter. Naturally she demurred. The correction of a very marked deviation of the nasal septum resulted in making the passage of the catheter perfectly easy, and subsequent treatment restored her hearing.

I am, Sir, yours faithfully,

MACLEOD YEARSLEY.

Wimpole-street, W., Jan. 15th, 1928.

To the Editor of THE LANCET.

SIR,—The view taken by skilled otologists of the operation is clearly shown and, if I may say so, very nicely put, in your correspondence column of last

week. It would be easy, but is hardly necessary, to add to the technical objections there made. Whenever any alleged new remedy for anything is promulgated (particularly when as in this case it gets into the lay press), what is likely to be the natural effect upon the public? For one thing, premature if not quite baseless hopes are raised. Since the publication of this new cure for deafness in "ears healthy except for deafness," I, as doubtless all your correspondents, have been bombarded with questions: Is it any good? Do you recommend it? Will you do it? and so forth. This public aspect of the matter has not so far been mentioned and is clearly a very important aspect. I join with the others in calling for further information and in the meantime shall continue to be guided by experiences which are precisely the same as those of your recent correspondents, so far as alleviation or cure of deafness by a fistula is concerned.

I am, Sir, yours faithfully,

T. JEFFERSON FAULDER.

London, W., Jan. 16th, 1928.

To the Editor of THE LANCET.

SIR,—I am loath to condemn Major Nesfield's suggested operation for the alleviation of deafness, but having contended with Eustachian tubes and middle ears for 40 years is the excuse for my making these remarks. If his cases of deafness were only caused by Eustachian stenosis why make a false passage to ventilate the middle ear, instead of opening the tube? In every case of deafness it is essential to make sure the tube is functioning properly; if it is not, to make it do so. The action of the tube with its accompanying muscles is of a very complex nature, and no false passage directly communicating with the atmosphere can take its place. As so many forms of deafness exist—the conditions of the tube and surrounding tissues all varying in character—it would be interesting to know what class of case Major Nesfield proposes to attack. It would be necessary also to know how the condition of the tubes was examined. These are only a few of the points I would like to remark on. I am, Sir, yours faithfully,

CLAUD WOAKES.

Park-square West, N.W., Jan. 17th, 1928.

FATALITY-RATES OF SMALL-POX IN THE VACCINATED AND UNVACCINATED.

To the Editor of THE LANCET.

SIR,—Dr. Garrow's inquiry *re* the above is very easily answered.

It is generally known that the immunity conferred by vaccination lasts for a limited time only. The period is variously estimated as between 10 and 13 years. By selecting cases over 15 Dr. Garrow is careful to include all cases vaccinated in infancy, but no longer protected. His statement that "the fatality-rate among vaccinated cases was just five times as great as among unvaccinated cases" is therefore grossly misleading.

It is, in my opinion, most regrettable that a medical man occupying a responsible position should broadcast in the medical press such an assertion which he must be aware will be quoted on his authority and without context by the antivaccinist press. This kind of action can do nothing but handicap his colleagues, who are engaged in combating the present epidemic of small-pox with its serious burden on the public funds, the loss of wages involved, and the damage to industry, quite apart from the detriment to public health, which in my recent experience is becoming more serious as the infection is passed through the human medium.

I am, Sir, yours faithfully,

FRED. E. WYNNE,

Jan. 16th, 1928. Medical Officer of Health, Sheffield.

ORAL ADMINISTRATION OF INSULIN.

To the Editor of THE LANCET.

SIR,—In the leading article on the Treatment of Diabetes in THE LANCET of Sept. 3rd, 1927, it is said that: "Attempts to secure a form of insulin which acts after oral administration have so far proved ineffective . . ." This statement proves certainly true for the ordinary preparations of insulin and is also in perfect harmony with the general opinion among physicians—in England. In other countries, however, many a doctor has, for years already, become accustomed to the internal application of insulin and quite a number among them, diabetics themselves, are using insulin pills regularly ever since and are very satisfied with the result. Several hundreds of reports, that have been graciously put at my disposal by colleagues thoroughly acquainted with the oral application of insulin, are unanimous about its antidiabetic as well as its roborant effect; within 8–10 days of such treatment the output of sugar with the urine diminishes gradually and remarkably, the average saving being 80 g. pro die, whereas the greatest amount observed till now has been as much as 270 g. pro die. The pain of thirst and other complaints disappear already during the first days of treatment, and as a rule the patient becomes fit again for work within the first fortnight. The patients, of course, have to observe a certain diet, but no change of diet is allowed after the beginning of the internal insulin treatment, so that any decrease of the glycosuria can only be attributed to the influence of the insulin itself.

As I am quite aware of the strange fact that, unlike in other sciences, in medicine ever so many genuine and authentic testimonials of colleagues carry but little weight with them in the opinion of other doctors, especially foreign ones, I should be delighted to enable any English colleague who wants to repeat the above-mentioned experiments to do so by putting at his disposal any amount of insulin pills. In putting the oral insulin on trial it must be remembered that its indications as well as its effects differ in several respects greatly from that of the injected insulin. Whoever would expect the insulin pills to act as quickly on the glycosuria, or as strongly on the glycæmia, as the injected insulin must necessarily become disappointed. The effect of the orally administered insulin on the glycæmia is, in fact, to be compared with that of the physiologically produced hormone of the pancreas; neither of them causes any leap of the concentration of the sugar in the blood, and both of them try to keep it at a certain level.

Regarding the indications of the oral application of insulin it is advisable to exclude two big categories of diabetics—those who ought to get injections of insulin and those who are able to observe always a diet that makes their glycosuria disappear. The remaining (medium) category of diabetics is not as unimportant as one might be inclined to think judging from hospital observations only; in fact, it is numerous enough to allow a fair trial of the possibility of a successful oral treatment with insulin. To begin with it can do them no harm whatever, and, judging from the many cases that have been under permanent medical observation for two or three years, the progress of their disease will be checked, their glycosuria diminish, their complaints disappear, and their efficiency for work be restored—a result that seems to be quite important enough, if not for the specialist, certainly for the general practitioner and his clients.

The insulin used in all the experiments mentioned above and partly published in foreign medical journals is, as already pointed out, not the usual one, but a specially concentrated one with the addition of purified ox-bile, that according to Besredka facilitates the intestinal resorption, and according to Landois checks the destroying influence of the trypsin on the

insulin. The antidiabetic effect of one of these insulin pills corresponds to four international units of insulin. I am, Sir, yours faithfully,

Saarbruecken. F. W. FORNET, M.D.

*** Dr. Fornet encloses extracts from German medical journals published during the last twelve-month and dealing with the results of insulin taken by the mouth. Apparently no determinations were made of blood-sugar, and it seems to have been a mild form of diabetes with which the several clinicians were dealing. In this country we are well aware that the mild forms of diabetes are readily influenced by changes in diet which it is difficult entirely to rule out. The work of Harrison, Lawrence, and Graham showed that no effect was produced on the blood-sugar by administering raw pancreas by the mouth when the diet was under perfect control. If it is admitted that insulin may have some effect on blood-sugar in rabbits and dogs when given by mouth with saponin, it seems that in the human subject the dose of saponin has to be relatively larger to produce any result at all, and even then the results are very variable.—ED. L.

THE TREATMENT OF THE MALARIAS.

To the Editor of THE LANCET.

SIR,—The introduction of any new drug of potential value in the treatment of malaria is an event of the first importance in tropical medicine, so it is very natural that it will be subjected to a considerable amount of criticism and claims of its efficacy regarded with scepticism. This is only as it should be. A study of the history of specific drugs reveals much the same sequence of events. The initial results are too often painted couleur-de-rose and therapeutic doses exhibited too large. This was so in the case of quinine itself, more recently in that of salvarsan and carbon tetrachloride.

A perusal of your leading article of Jan. 14th (p. 87) has led me to make some observations in order to remove misapprehensions. The writer of that article, though well versed in the literature of the subject, has obviously had no first-hand experience of plasmochin (or plasmoquine) in the treatment of malaria. As I pointed out in my original paper,[1] "The action of Plasmochin in Malaria," the initial doses of the drug as advocated by Mühlens were too large, thereby predisposing to symptoms of intoxication, especially in the subtertian form of malaria. There can be no doubt, however, from the observations of other workers as well as my own that this drug exerts a specific action on the gametocytes of the benign as well as of the subtertian forms. In an acute disease such as the latter form of malaria it is very difficult indeed to be certain whether alarming symptoms which may develop are due to the parasite itself or to the drug. It is a familiar experience that the same difficulty is encountered with quinine, but when plasmochin is combined with small doses of quinine (i.e., plasmochin-compound) the toxic effects of the former are counteracted and, in my experience, no untoward symptoms are encountered. This I have stated emphatically in my paper in THE LANCET of Jan. 7th (p. 25). The series of cases quoted there is comparatively small, but I have exhibited the drug to some 100 other individuals in whom, for one reason or other, no detailed records could be kept. In no instance have I encountered genuine intolerance and most certainly I have not seen any fatal or alarming symptoms, nor have I heard of such. In any new departure such as this these exaggerated statements are bound to be made. In addition to removing or neutralising the toxic element plasmochin-compound has the same startling effect upon the gametocytes, especially on the crescents of subtertian malaria, and it is (probably from the contained quinine) much more effective in acute subtertian cases with numerous ring forms (or schizonts) in which parasitic relapses used to occur on the pure plasmochin treatment. In no case which I have had under observation have the crescents recurred in the peripheral blood after their primary disappearance, and my records have been very carefully kept. It is true that plasmochin-compound has been issued in two forms. The first was purely experimental; the larger tablets each contained 0·01 g. plasmochin and 0·125 g. quinine sulphate. The second now on the market contains half that amount—i.e., 0·005 g. plasmochin and 0·0625 g. quinine sulphate. Your reviewer is clearly in error on this point, as he has quoted figures twice this size, and his statement on this point needs correction. The daily dosage I would advocate as the result of my recent investigations is one of 0·06 g. plasmochin plus 0·75 g. quinine sulphate (i.e., gr. 9¼ or twelve of the plasmochin-compound tablets). Every clinician experienced in tropical medicine is agreed that the latter dose of *uncombined* quinine is too small to control a bad attack of malaria and is certainly inoperative upon the crescent form.

Whatever the value of conflicting testimony may be it is abundantly clear that a new specific has been introduced into our armamentarium quâ malaria. More extensive experience on its use will no doubt modify the dosage, and it is too early yet to say how far-reaching the importance of this discovery may be, but for those who are dissatisfied with the shortcomings of pure quinine (and their name is legion) the introduction of plasmochin is a step in the right direction. I am, Sir, yours faithfully,

PHILIP MANSON-BAHR, M.D., F.R.C.P.,
Physician to the Hospital for Tropical Diseases,
Jan. 17th, 1928. London.

[1] Proc. Roy. Soc. Med., 1927, xx., 919.

To the Editor of THE LANCET.

SIR,—Perhaps one reason why there is a shortage of quinine is that, being regarded as a "cure" for malaria, it is prescribed in large and continuous doses which involve much waste of the drug and many examples of cinchonism. As treatment quinine is, of course, invaluable, but the cure of malaria depends on the ultimate development of sufficient immune bodies to control the plasmodium in all its forms. I suggest that grs. 20 is an ample maximum daily dose, and that, when after four days the patient has lost his fever and is convalescent, he should be allowed a rest from quinine in order that all traces of the drug may be excreted and, in order that his own defence forces may have an opportunity of taking part in the fight for the patient's complete restoration to health the administration of quinine being continued on these lines for a sufficient period but with a gradual decrease in the days of taking and an increase in the days of rest from quinine.

Put shortly, I urge that quinine should be given intermittently for the following reasons: (1) Cinchonism in its many forms is mostly avoided (2) as a result of (1) patients continue their treatment (3) there is a great saving—amounting to nearly 50 per cent.—in the amount of quinine used; (4) the case-results are very satisfactory.

I am, Sir, yours faithfully,

London, Jan. 17th, 1928. V. S. HODSON.

RECURRENT COLDS.

To the Editor of THE LANCET.

SIR,—Some of your recent correspondents on the above subject have spoilt a good case by over-statement. "Cold-catching" seldom troubles those who live in a well-managed open-air sanatorium but they do not find it necessary to dispense with underclothing, excepting in very hot weather. Three points are of importance: training to react against chill; avoidance of excessive infection from without and the removal of infective foci within the body. Such training should be carried out with due regard

the individual reactive capacity at the time; we annot all, or in all states of health, bathe with mpunity in the ice-covered Serpentine. Overheated, nderventilated places, and those with an unvarying emperature, are risky for most people. To avoid utside infection much greater care should be taken n removing household dust than is usual in most omes, preferably by wet cleaning. But the greatest rotection is an open-air life, with a little common ense. I am, Sir, yours faithfully,

Farnham, Jan. 16th, 1928. F. R. WALTERS.

Obituary.

REDERICK GORDON BROWN, M.R.C.S., L.S.A.

THE death is announced at the advanced age of 85 Dr. Frederick Gordon Brown, who practised in the ty of London for many years and who died at ailours, Chigwell, Essex, on Sunday last, Jan. 15th. he son of a doctor who practised in Wormwood-street, .C., Gordon Brown was born in the City, and educated Merchant Taylor's School. He received his medical lucation at St. Thomas's Hospital, where he held sident appointments after qualification in 1863. He en attended post-graduate courses in Paris before tering upon practice. He soon won for himself a od position, and for 52 years was a medical officer of e City of London Union and for over 28 years surgeon the City of London police. He was also formerly rgeon to the Royal Hospital, Bridewell, and the ildhall School of Music, so that his associations th the City were many and intimate. He was for any years in partnership in Finsbury-circus with . A. P. Gibbons, and although he retired in ptember, 1914, he acted for various younger men ring the war in order to release them for war service. e was at the time of his death the Senior Past Master the Society of Apothecaries, and a past president the Hunterian Society. He was also a prominent eemason, being a Past Grand Officer of the Grand dge of England.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Capt. J. R. Muir is placed on the Retd. List with nk of Surg. Rear Admiral.

To be Surg. Lts.: J. A. K. FitzGerald, J. W. Nesbitt, D. Sinclair, E. R. P. Williams, and A. E. Kingston.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. D. S. Skelton from the secd. list is restd. to the abt.

Capt. J. H. Bayley to be Maj.

Lt. W. D. Speedy resigns his commn.

ARMY DENTAL CORPS.

Lt. D. C. Blyth to be Capt.

Temp. Lt. A. Brazenor, Dental Surg., Gen. List, to be Lt.

TERRITORIAL ARMY.

Maj. J. Wallace, from T.A. Res. of Off., to be Maj.

Capt. W. W. Brown, late R.A.M.C. (Spec. Res.), to be pt.

Capt. (Prov.) R. N. Craig is confirmed in his rank.

Lts. A. C. Crawford, D. R. Owen, and C. E. W. Bower be Capts.

Lt. R. Walkingshaw resigns his commn.

C. C. Ryan to be Lt.

Supernumerary for service with O.T.C.: Capt. J. F. Smith igns his commn.

ROYAL AIR FORCE.

Flying Officers promoted to the rank of Flight Lt.: I. Hyder and J. Magner.

Flight Lt. F. K. Wilson is transferred to the Reserve, ss D.II.

Flight Lt. (Hon. Squadron Leader) E. F. N. Currey relinquishes his temporary commission on completion of service.

Flying Officer F. S. S. Whiter is promoted to the rank of Flight Lt. (Dental) on promotion to Captain in the Army Dental Corps.

AUXILIARY AIR FORCE.

No. 601 County of London (Bombing) Squadron: Pilot Officer E. D. W. Reid to be Flying Officer.

INDIAN MEDICAL SERVICE.

Lt.-Cols. J. D. Graham, M. MacKelvie, and W. H. C. Forster to be Cols.

Lt. J. H. Clapp to be Capt. (Prov.).

Lt.-Col. T. S. Novis retires.

DEATHS IN THE SERVICES.

Lieut.-Colonel Paxton St. Clair More, O.B.E., late I.M.S., who died at Bournemouth on Jan. 8th, aged 61, graduated in medicine and surgery at Edinburgh University in 1891, where he was for a time assistant demonstrator of practical physiology and pathology. He entered the Indian Medical Service and was at the Relief of Chitral in 1895. He also served in Iraq, and in 1920 was mentioned in dispatches and was awarded the O.B.E.

Medical News.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a meeting of the Council held on Jan. 12th Sir Berkeley Moynihan, the President, in the chair, diplomas of Membership were granted to the following:—

Eleanor M. Carless, Royal Free Hosp.; Abani Mohan Chaudhuri, Calcutta and St. Bart.'s; Thomas E. Lamech, Cambridge and St. Thomas's; Mary M. Moller and Lois J. Ogle, Royal Free Hosp.; and Pattiyapotherannehelage Paul Peries, Ceylon and King's College.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH.—The Morison lecture will be delivered at the College on Wednesday, Jan. 25th, by Dr. George M. Robertson. His subject will be the Teaching of Psychiatry in Edinburgh and Sir Alexander Morison.

UNIVERSITY OF SHEFFIELD.—At examinations held recently in the Faculty of Medicine, the following candidates were successful:—

M.D.—Marion Hirst.

Final M.B., Ch.B. Examination.—Part II.: Humphrey Brookes, Albert O. Flint, Patrick B. Lee-Potter, and Vernon E. A. Marwood. *Part I.:* William Alcock, Doris Butler, Dorothy Colver, Reginald D. Dewar, Traugott E. Gumpert, Kenneth J. G. Milne (with distinction in Public Health), Trevor K. Owen, Geoffrey B. Thomas, Walter A. Timperley, and Joan J. J. Wallace.

UNIVERSITY OF LIVERPOOL.—At a recent examination the following candidates were successful:—

DIPLOMA IN PUBLIC HEALTH.

V. H. Atkinson, Annie T. Deane, Sybil O. Edwards, and A. N. Malhotra.

PREVENTION OF INDUSTRIAL ACCIDENTS.—A conference on Accident Prevention is to be held under the auspices of the Industrial Welfare Society at the Hotel Metropole, Northumberland-avenue, London, on Friday, Jan. 27th. Details may be had from Mr. G. P. Holden at 151, Palace-street, S.W. 1.

The fifth International Medical Congress for Industrial Accidents and Occupational Diseases is to be held in Budapest from Sept. 2nd to 8th. The Executive Committee consists of Prof. Tibor de Verebély (President), Prof. William de Friedrich (vice-president), and Dr. George Gortvay (secretary general). Addresses will be given, amongst others, by Prof. J. Liniger, Dr. F. Zollinger, Prof. K. B. Lehmann, Sir Thomas Oliver, Prof. J. G. Sleeswijk, Prof. Jütten, Prof. Koelsch, Prof. Julius van der Hoeve, and Prof. Stephan Jellinek. Although industrial diseases will receive consideration, particular prominence will be given in the programme to industrial accidents, as in 1929 a congress specially devoted to diseases is to be held in Lyons under the auspices of the Congress for Occupational Diseases. The Council of Industrial Medicine has been nominated to act as the British National Committee, and further information can be had from the Secretary, 12, Stratford-place, London, W. 1.

UNIVERSITY OF LONDON: *University College.*—A course of six lectures on the Internal Secretions of the Gonads will be given by Mr. A. S. Parkes, D.Sc., on Mondays, Jan. 30th, Feb. 6th, 13th, 20th, and 27th, and March 5th, at 5 P.M. Admission will be free, without ticket.

UNIVERSITY OF MANCHESTER.—Prof. J. S. B. Stopford, F.R.S., has been appointed a Pro-Vice-Chancellor of the University.

RESEARCH ON THE COMMON COLD.—The sum of £39,000 has been given to Johns Hopkins University, Baltimore, to pay for research into the origin, nature, and possible cure of the common cold.

THE SUPPRESSION OF QUACKERY.—The California Medical Association has received under the will of the late Dr. Morris Herzstein a bequest of 20,000 dollars to be used in the suppression of quackery in the practice of medicine.

POST-GRADUATE STUDY IN BERLIN.—A programme of numerous courses of lectures to be held in March and April has now been issued by the Kaiserin Friedrich-Haus, Luisenplatz, 2–4, Berlin, N.W. 6. This organisation assists foreigners to secure suitable lodgings, and can also arrange visits to clinics and hospitals.

CENTRAL ASSOCIATION FOR MENTAL WELFARE.—A special ten weeks' course is being held in London from May 11th to July 19th for teachers of mentally defective and of dull and backward children. It is intended for those with no previous experience of the work. Since 1925 three similar courses have been arranged by the Association with the full approval of the Board of Education.

ROYAL NATIONAL ORTHOPÆDIC HOSPITAL.—A Festival Dinner will be held on Monday, Jan. 30th, at the Mansion House, London, by invitation of the Lord Mayor. Prince Henry will preside. An effort will be made to raise funds to pay off the debt of £40,000 created by extensions at the country branch at Stanmore.

AMALGAMATION OF WOLVERHAMPTON HOSPITALS.—It is proposed to amalgamate the Wolverhampton and Staffordshire Hospital and the Wolverhampton Hospital for Women, and the Hospital Saturday Committees of the two institutions have unanimously approved of the scheme on the ground that it will provide a more efficient service. The general hospital at present has 210 and the women's hospital 30 beds, but enlargements in progress at both institutions will increase the accommodation approximately to 300 beds.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Dr. W. A. Potts will lecture on Mental Defect and its Importance to the Community, on Monday, Jan. 23rd, at 5 P.M., at the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square. On the same date, at 3 P.M., at the Royal Eye Hospital, Southwark, Mr. McCallan will give a clinical demonstration, and Mr. Mortimer Woolf a general surgical demonstration at 2 P.M., at the Queen Mary's Hospital, Stratford. On Thursday, Jan. 26th, at 1.30 P.M., Sir Thomas Horder will demonstrate at St. Bartholomew's Hospital. The lectures and demonstrations are open to members of the medical profession without fee. Six lecture-demonstrations on Psychological Medicine, held on Tuesdays and Saturdays at 11 A.M., at the Bethlem Royal Hospital, have still to be given. From Feb. 6th, for four weeks, a course in Venereal Diseases will be given at the London Lock Hospital, consisting of lectures and clinical instruction in the out-patient department. Early application should be made. From Jan. 30th to Feb. 25th a course will be held at the London School of Dermatology (St. John's Hospital); clinical instruction will be given in the out-patient department every day, and lectures on Tuesdays and Thursdays at 5 P.M. (practical pathological demonstrations can also be arranged). An all-day course in Diseases of Children will be given from Feb. 6th to 18th at the Paddington Green Hospital and at the Victoria Hospital for Children; sessions at the former hospital will be held on Feb. 7th, 8th, 10th, 13th, and 17th, and at the latter on Feb. 6th, 9th, 11th, 14th, 15th, and 18th. Early application is requested. From Feb. 20th to March 3rd, at the Queen Mary's Hospital, Stratford, an all-day course will be given in medicine, surgery, and the specialties. From Jan. 30th to March 23rd, at the National Hospital, Queen-square, a course will be held in neurology, anatomy, and physiology of the nervous system, and demonstrations will be given on methods of clinical diagnosis in diseases of the nervous system and in pathology. Information, syllabuses, tickets, and copies of the *Post-Graduate Medical Journal* may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

PRESENTATION TO A MEDICAL MAN.—Dr. Edwar Fielden was recently presented with a cheque and a illuminated book containing the names of 1400 people wh wished to show their appreciation of his services durir more than 25 years of practice at Bracknell, in Berkshire.

LIVERPOOL HOSPITAL FOR DISEASES OF THE HEAR Miss Margaret Beavan, Lord Mayor of Liverpool, last wee opened a new operating theatre and an additional ward t mark the second anniversary of the opening of the institu tion. The extension increases the number of beds to 3 The Lord Mayor was presented with a silver casket as souvenir.

IMPORTATION OF SYNTHALIN.—The Board of Trad have given notice that representations have been made t them under Section 10 (5) of the Finance Act, 1926, regardir hydrocyanic acid and synthalin (Deka methylene diguanidin hydrochloride). This section provides that the Treasur may exempt from the duty imposed by the Safeguarding Industries Act, 1921, any article which is not made in an part of His Majesty's Dominions in quantities which a substantial, having regard to its consumption for the tim being in the United Kingdom, if there is no reasonab probability that it will within a reasonable period be ma in His Majesty's Dominions in such quantities. Any perso wishing to communicate with the Board about this applic tion should write to the Principal Assistant Secretar Industries and Manufactures Department, Board of Trad Great George-street, S.W. 1, before Feb. 12th.

Medical Diary.

Information to be included in this column should reach in proper form on Tuesday, and cannot appear if it reac us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Jan. 23rd.—8 P.M., ODONTOLOGY. Pap Mr. Arthur Bulleid: On Apical Infection; Cas communications: Mr. H. P. Baylis: Case of Necro of the Mandible. Mr. W. Rushton: An Abnorma Small Premolar.

TUESDAY.—5 P.M., MEDICINE. Discussion on Card Infarction (Coronary Thrombosis). Openers: John Parkinson and Dr. D. Evan Bedford. Ot Speakers: Dr. Carey Coombs, Dr. Geoffrey Hadfi Dr. J. A. Ryle, and Dr. B. T. Parsons-Smith.

WEDNESDAY.—5 P.M. TROPICAL DISEASES, DERMATOLO AND COMPARATIVE MEDICINE. Special Discussion Cutaneous Mycoses in the Tropics. Openers: Mr Ramsbottom (for the Section of Tropical Diseas Dr. A. Whitfield (for the Section of Dermatology

THURSDAY.—5 P.M., BALNEOLOGY. Paper: Dr. Ado Schott (Bad Nauheim): Carbon Dioxide Ther Saline Springs in the Light of Modern Resea 8.30 P.M., UROLOGY. Clinical Pathological Evening

FRIDAY.—5 P.M., DISEASE IN CHILDREN. (Cases 4.30 P.M.) 8 P.M., EPIDEMIOLOGY. Paper: Dr. J. McCartney and Dr. Wm. C. Harvey: Some Obse tions on Diphtheria Carriers.

MEDICAL SOCIETY OF LONDON, 11, Chandos-str Cavendish-square, W.

MONDAY, Jan. 23rd.—8.30 P.M., Discussion on Treatmen Pernicious Anæmia, to be introduced by Prof. F. Fraser, followed by Sir William Willcox and Dr. French.

MEDICO-LEGAL SOCIETY.

THURSDAY, Jan. 26th.—8.30 P.M. (at 11, Chandos-st Cavendish-square, W.), Mr. F. Llewellyn-Jon Drunkenness and Civil and Criminal Responsibilit A Study in Comparative Law.

MEDICAL SOCIETY FOR THE STUDY OF VENEREL DISEASES, 11, Chandos-street, Cavendish-square, W.

FRIDAY, Jan. 27th.—8.30 P.M., General Meeting. Pa will be read by Colonel L. W. Harrison and Dr. D Nabarro on the Antenatal Treatment of Vene Disease—Syphilis. A discussion will follow.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIE FRIDAY, Jan. 27th.—4.15 P.M. (at St. John's Hosp 49, Leicester-square, W.C.), Clinical Cases.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c

FELLOWSHIP OF MEDICINE AND POST-GRADUA MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 23rd, to SATURDAY Jan. 28th.—FELLOW OF MEDICINE Lecture at the Medical Society, Chandos-street, W. Mon., Dr. W. A. Potts: Mental Defect and its Importance to the Communit QUEEN MARY'S HOSPITAL, Stratford, E. Mon., 2

Mr. Mortimer Woolf: General Surgical Demonstration.—ROYAL EYE HOSPITAL, Southwark, S.E. Mon., 3 P.M., Clinical Demonstration by Mr. MacCallan. The above are free to members of the medical profession.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E. Course in Psychological Medicine. Lecture-demonstrations Tues. and Sat., at 11 A.M.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, W.

MONDAY, Jan. 23rd.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Dr. Trevor Davies: Gynæcological Department.

TUESDAY.—2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. MacDonald: Genito-urinary Department. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Special Medical Treatment Clinic. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department. 4.30 P.M., Dr. Archer: Carbohydrate Tolerance Tests (lecture-demonstration).

SATURDAY.—10 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Owen: Medical Diseases of Children.

Medical and Surgical Out-patients, Operations, Special Departments, daily, 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 1 P.M.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham.

MONDAY, Jan. 23rd.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Jan. 24th.—5 P.M., Dr. W. J. O'Donovan: Exfoliative Dermatitis.

THURSDAY.—5 P.M., Dr. Knowsley Sibley: Electrotherapeutics.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Jan. 23rd.—1.30 P.M., Mr. R. J. Cann: Examination of the Pharynx and Naso-pharynx.

St. John's Hospital, Lewisham.—Asst. P.
St. Mary's Hospital for Women and Children, Plaistow, E.—Res. M.O. and Asst. Res. M.O. At rate of £175 and £130 respectively.
Salford, City of.—Venereal Disease M.O. £750.
Shanghai Municipal Council Public Health Dept.—Asst. Radiologist. Taels 700 a month.
Sheffield Royal Hospital.—Res. Anæsthetist.
Shrewsbury, Royal Salop Infirmary.—H.P. £160.
Sleaford, Kesteven Mental Hospital.—Asst. M.O. £350.
Stoke-on-Trent City Maternity Home.—Res. M.O. £450. Also Consulting Officer. £150.
Stoke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Hon. Asst. S., Hon. Anæsthetist, Hon. Asst. Aural S., and Hon. Asst. Orthopædic S.
Truro, Royal Cornwall Infirmary.—H.S. £170.
West London Hospital, Hammersmith-road, W.—Hon. Obstet. S.
Windsor, King Edward VII. Hospital.—Hon. Asst. Phys.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.
Woolwich and District War Memorial Hospital, Shooters' Hill, S.E.—Radiographer.

The Secretary of State for the Home Department gives notice that he is considering the appointment of one or more Ophthalmic Specialist Medical Referees under the above Act for County Courts in Circuits 16 and 17, which comprise roughly the East Riding of Yorkshire and Lincolnshire. Applications should be addressed to the Private Secretary, Home Office, London, S.W. 1, and should reach him not later than Feb. 7th, 1928.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Islay (Argyllshire), Wallingford (Berkshire), Fyvie (Aberdeenshire), Portree (Inverness-shire), and at Wetheral (Cumberland).

Births, Marriages, and Deaths.

BIRTHS.

DOYLE.—On Jan. 10th, at Old Bromley-road, Bromley, the wife of Dr. J. L. C. Doyle, of a daughter.

PERRIN.—On Jan. 12th, at Upper Wimpole-street, W., the wife of W. S. Perrin, F.R.C.S., of a daughter.

THOMAS.—On Jan. 11th, at Ashley-gardens, S.W., the wife of C. Price Thomas, F.R.C.S., of a son.

DEATHS.

BROWN.—On Jan. 15th, at Tailours, Chigwell, F. Gordon Brown, M.R.C.S., late surgeon of the City of London Police, Past-Master of the Society of Apothecaries, aged 85. Funeral at Chigwell to-day (Friday) at 3.15 P.M.

DINNIS.—On Jan. 15th, at Leigh Croft, Hoddesdon, Alfred Dinnis, M.R.C.S., L.R.C.P., L.D.S., aged 47.

MORE.—On Jan. 8th, Lieut.-Col. St. Clair More, O.B.E., I.M.S., at Bournemouth, aged 61.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

PALÆOPATHOLOGY AND EVOLUTION.*

By J. C. M. GIVEN, M.D., M.R.C.P. LOND., F.G.S.

THE great interest that has been taken of recent years in the history of medicine has resulted in much research and in the classification and publication of many important facts, all of which, however, are more or less confined to the historic period of which written records are available. The allied subject of the antiquity of disease is much more difficult to explore, as the chief evidence consists of the fossil remains, usually fragmentary, of a long-departed fauna.

Yet the more such evidence is collected and sifted the more it shows that disease in its protean manifestations has been a powerful agent in the elimination of the unfit, and the survival and persistence of the predominating types of life in the evolutionary struggle, and that insufficient credit has hitherto been given to this factor.

It is interesting to note that the most important causative agents of disease that we recognise to-day—namely, bacteria—were the earliest known forms of life. They probably prepared both the earth and the ocean for the further evolution of plants and animals. The fact that they did exist at this epoch was proved by Walcott [1] in 1915, when he found micrococci associated with very primitive algæ in the pre-Cambrian limestones of the Algonkian Mountains, the earliest sedimentary rocks of which the earth is built. This is only what we should expect when we consider the cyclical processes of life in the universe. All plant life depends on the nitrifying bacteria of the soil for the nitrates with which to build up its proteins; the plants are devoured by animals and new proteins are built up, and the completion of the cycle is only made possible by putrefactive organisms breaking down the nitrogenous animal tissues into free ammonia. The first lowly bacteria derived their energy and nutrition from inorganic chemical compounds such as the ammonia salts; they were, according to Osborn [2] the first step between the organic and the inorganic, and represent the survival of a primordial stage of life's chemistry. Survivors of these bacteria still persist in the nitrifying soil organisms just alluded to.

The early microbes first began a parasitic life by symbiotic relations with other bacteria; then they laid hold on the chlorophyllic carbon-storing plants, stealing carbon from the plant and nitrogen from the atmosphere, and thus started on the path which led from symbiosis to parasitism, and thence to that of pathogenic infective agents, though the last stage probably took long ages to reach.

Adami [3] points out that microbes do not form an order by themselves, but are singularly diverse in their affiliations. Whether bacteria or protozoa like the spirochætes, every pathogenic microbe has closely related forms or species, differing from them in little beyond the fact that one is virulent and that the other is not. This leads to the conclusion that all the pathogenic germs have originated in harmless saprophytes. The non-virulent diphtheroid organisms, the bane of the diagnostician, probably long preceded the Klebs-Löffler bacillus.

The Evolution of Pathogenic Bacteria.

The evolution of the various strains of these minute organisms results from changing environment, just as it does among the higher forms of life. The colon bacillus leads a harmless and probably a useful life in its native pastures of the large bowel, but when it migrates into the urinary tract it becomes endowed with very different characteristics. Similarly, in Devonian times, before our coal measures were laid down and when fishes were the sole representatives of the vertebrata, some of these, hankering after a change of scene, migrated to the land and became first amphibia, and later reptilia, which were the basal stock of the mammalia. The two processes are identical, though one, acting on a minute simple monocellular organism, may have only taken hours to bring about; the other, working on a complex vertebrate, required millions of years. This rather crude analogy may be pushed further. Bacteriologists tell us that the wandering bacilli may, by various cultural methods, be enticed back to dwell in similar surroundings to their old ones. In the same way some of the mammalia, probably in the African continent, got tired of their existence on dry land, and early in the Tertiary period reverted to a life in the ocean and became whales, dolphins, and porpoises, but retained indelible traces of their terrestrial life and mammalian origin, just as, probably, our colon bacill is never quite the same again after first leaving the intestin tract.

Bacteria do not seem to have taken on pathogen qualities until forms of life had become numerous ar varied, and their agency was not required for many millio of years as a factor in the process of natural selectio Fossils can afford little evidence of this kind, and when l was only represented by the polyzoa and the higher forms the invertebrata, such as molluscs and arthropods, it probable that traumatism, degenerative changes, and t consumption of each other as food would represent all t ills to which individuals were subject. By the time co measures were formed bacteria seem to have establishe themselves as saprophytes on the fishes of that age, Renault [4] has demonstrated them in coprolites, or fos fæces, in the Autun coalfields of France. This is perhaps instance of an early intestinal flora, the first appearance prototype of the colon bacillus. Renault also figures micrococcal type of organism in the lacunæ and canalic of the bones of fossil fishes in these coal measures. This the earliest hint of the existence of pathogenic infection.

Fossil Pathology.

From the Permian strata of Texas Roy Moodie [5] descril a microscopic section of the fractured dorsal spine of reptile, Dimetrodon, which he considers to be a case infective osteomyelitis, showing osseous trabeculæ arou large necrotic sinuses, once filled with pus and now replac by calcite crystals. This is probably the earliest kno instance of the presence of pathogenic bacteria, for t specimen must be at least 15 million years old. Anot instance by the same author [6] from a slightly later peric the Cretaceous, when our chalk downs were being form shows necrotic changes in the radius of a large aqua reptile with the formation of dense hypertrophic bone, t normal vascular spaces having been obliterated.

As an example of a simple uninfected fracture wi normal union and a moderate degree of callus we may ta the fractured radius of another reptilian Dimetrodon fr the same Permian beds.[5] A further interesting specimen i tumour in the caudal vertebra of a Diplodocus of Cretaceo age, described by Moodie as an hæmangioma. The enormous reptiles, nearly 70 ft. long and weighing appro mately 40 tons, dragged their gigantic 30 ft. tails along t ground and must have been much subject to traumatis Moodie also mentions a tumour of the jaw of a primiti horse, *Merychippus campestris*, of Miocene age, a lesion wh was evidently of long-standing and which suggests acti mycotic infection.

The earliest known human skeleton has a pathologi lesion; the femur of *Pithecanthropus erectus* of Java sho a large irregular outgrowth from the shaft, evidently of t nature of myositis ossificans. Though the geological horiz of the Rhodesian skull is uncertain, it is undoubtedly ve ancient, and is of extreme Neanderthaloid type. There a deep irregular sinus in the petrous portion of the t temporal bone just behind the external auditory meat Tracking upwards and slightly forwards from this is shallow groove on the squamous portion, and just in fr of the termination of the groove is a circular hole which g right through the squama into the cranial cavity; the ed of this foramen are quite smooth, and it must have be made ante-mortem. Macleod Yearsley declared that the abnormalities were due to mastoid disease, and it is fai obvious that the mastoid abscess opened behind the exter auditory meatus and tracked upwards and forwards un the temporal muscle. There is a second bony sinus at tip of the mastoid process, so that it must also have oper into the muscles of the neck. Some suppose that circular smooth opening is a primitive piece of cran surgery, to drain the abscess and perhaps a deeper tempo sphenoidal one. Elliot Smith has suggested that the ma may have been caused by gnawing insects, such as co roaches, which, he states, often attack the bones of Egypt mummies; such an explanation, however, is not sa factory here, and cannot possibly be applied to the smo round hole in the squamous bone. Prehistoric cran trephining is a large subject; it was a common pract among some neolithic peoples and among the ancient tri of Peru. I would refer anyone interested in this matter Dr. Wilson Parry's [8] instructive address to the Lister Society of King's College Hospital, 1923. There is excellent exhibit of ancient skulls with trephine holes in Hunterian Museum of the Royal College of Surgeons England, and alongside has been placed the skull of first patient on which a successful operation for removal of a cerebral tumour was done. It was perform by Sir Rickman Godlee in 1884, after being diagnosed localised by Dr. Hughes Bennett.

Another well-known prehistoric skeleton showing pat logical changes is the Chancelade skeleton [9] in the muse

* Being the presidential address to the Liverpool Medical Institution, delivered on Oct. 13th, 1927.

t Perigeaux, from the Magdalenian deposits in the ordogne, probably about 10,000 years old. It shows an xtensive fracture of the right temporal bone which has ompletely healed. It also shows well-marked evidence of steo-arthritis in the shoulder-joints and dorsal spinal rticulations.

The Work of Marc Ruffer.

The subject of prehistoric human pathology was first eriously investigated by Sir Marc Armand Ruffer, who oined the term palæopathology. He was the first director f the British Institute of Preventive Medicine. While nvestigating the new antidiphtheritic serum in 1891 he ontracted the disease and suffered severely from paralytic equelæ; giving up his post, he went to Egypt to convalesce, nd settled there. He was the first to investigate the icroscopic structure of mummies, and he invented special ethods for cutting and staining this difficult material. fter his death his papers and studies were edited and ublished in 1921 by R. L. Moodie, professor of anatomy at he Illinois University of Chicago, under the title of "Studies n the Palæopathology of Egypt." The preface is a mine of nteresting facts. Ruffer was indebted for much of his naterial to Reisner, Elliot Smith, Wood-Jones, and Derry, ho had been assisting in an archæological survey, which the overnment of Egypt carried out in 1907, of that part of ubia about to be submerged by the Assouan Dam. The eport [18] drawn up by these gentlemen was published by he Egyptian Government in a series of bulletins containing nuch information on the pathology of the ancient population f that country. Some of the best specimens from this rvey form an interesting exhibit in the Nubian collection f the Hunterian Museum, and are well worth inspection; hey were shortly catalogued and described by Shattock, ho on one occasion exhibited before the Royal Society of edicine sections of the aorta of Meneptah, the reputed haraoh of the Hebrew Exodus, who died 1215 B.C.; the ction showed typical senile calcification, the elastic mellæ being perfectly preserved, and the interlamellar naterial thickly strewn with calcium phosphate.

One of the most interesting discoveries of Ruffer was the monstration of typical calcified eggs of *Bilharzia hæmatobia* the tubules of the kidney in two mummies of the XXth nasty; the rectum and bladder, however, were not fficiently preserved to show the condition. This form of histosomiasis with which now, according to recent authoriies, 60 per cent. of the inhabitants of Egypt are infected, as therefore present at least 1000 B.C.

One of the plates in this book shows an excellent example Pott's disease of the spine, with a well-marked psoas bscess from the mummy of a priest of Ammon of the XIst dynasty. Ruffer also figures a vesicular rash from he skin of a mummy of 1200 B.C. The distribution of the sh corresponds with that of small-pox, and the structure ows the dome-shaped vesicles in the prickle cell layers. he high-power photographs of the skin show a large number bacilli stained Gram-eosin. These presumably were condary, but this shows very well the preservation of ese organisms for many centuries.

A statuette, now in Cairo Museum, of an important court ficial, "head of the wardrobe," who lived in the Vth nasty, 2700 B.C., is a typical achondroplastic dwarf with e usual disproportion between the trunk and limbs. These arfs seem to have been fairly common in ancient Egypt; veral are figured on the monuments. The *Times* of pril 7th, 1927, describes the effigy of an individual called nab, 2900 B.C., recently discovered in a Mastaba tomb, hich, from the description, was another example of hondroplasia. Pigmies from Central Africa were also nployed by the ancient Egyptians, and any fantastic or normal dwarf was evidently highly prized for household rvice. Rickets and talipes are among the varieties figured. steitis deformans, or osteo-arthritis, occurred widely nong the early Egyptians; this is emphasised by Elliot nith and Wood-Jones in the Nubian Survey Report.[18] seems to have affected especially the spinal column. ere is a well-marked example (Flinders Petrie) of the ondylitic variety in an individual of the name of Nefermat, whom the whole spinal column, from the fourth cervical rtebra to the coccyx, has been converted by the disease o a rigid column; it has subsequently been broken into veral pieces. It was found in one of the early Mastaba mbs of the IIIrd dynasty about 3200 B.C., long before the e of the Pyramid builders.

From the catacombs of Alexandria, in the time of the man occupation, A.D. 250, Ruffer obtained an interesting ecimen of pelvic tumour. The ischium was greatly ckened and rounded and, on section, consisted of mpact dense bone with numerous cavities. He says it is arly not due to any of the infective agents, such as bercle or syphilis. He considers it to be an osteosarcoma, which we have only the bony remains left.

We may take it that there never was a time when mankind was not cursed by toothache. Dental caries is found in the early and late Stone Ages and was very common in the Bronze Age in Europe. Ruffer figures many cases from early dynastic times in Egypt.

Syphilis.

It is an interesting fact that no evidence of syphilis has been found amongst ancient Egyptian remains, and the origin of this disease is still shrouded in mystery.[10] At a special discussion on syphilis at the Royal Society of Medicine in 1912 [11] Norman Moore pointed out that the disease could not have been recognised in Roman times, for that keen observer Galen, with his careful descriptions of nervous disease, is quite silent as to the characteristics of locomotor ataxy or general paralysis of the insane. On the other hand, Voberg, of Stuttgart,[12] recognised the stigmata of the disease in certain early historical personages, such as Augustus Cæsar and Socrates. All the busts of the great philosopher show a marked retroussé nose with a defective bridge. The statuette recently discovered in Alexandria, dating from the fourth century B.C., is the earliest known representation of the sage, and must have been almost contemporaneous; it may, indeed, have been made from life. It has just been acquired by the British Museum [20] and demonstrates the condition very clearly.

Some have tried to find evidence of lues in the descriptions of disease in Holy Writ, such as the Emerods with which the Philistines were afflicted in their secret parts (I. Samuel, V. and VI.), but Adami [3] in his Croonian lectures attributes these lesions, and no doubt rightly, to bubonic plague.

It has generally been supposed that syphilis was not recognised in Europe until after the return of the sailors of Christopher Columbus from the discovery of America in 1493, the inference being that they brought it from that country. The well-known American anthropologist, Hrdlicka, of Washington,[19] on the other hand, in his extensive studies of hundreds of pre-Columbian skeletons in that country, states that he has never come across any condition suggestive of syphilis, while skeletons of American Indians of post-Columbian date show that the disease wrought fearful havoc amongst them. But this year Prof. Hayhurst,[13] of Ohio University, quotes the radiographic work of Dr. Means on the skeletons of the Mound builders of Ohio. These Mounds, or Tumuli, are now recognised as offshoots of the Aztec, and the still earlier Toltec cultures of Mexico, which in its turn was derived from the ancient Maya civilisation of Central America. Dr. Means states that he found "gross evidence of syphilis in these skeletons; they presented varying degrees of involvement, from simple periosteal thickening and roughening on the crests of the tibiæ to thickened ivory-like bone invading the medullary canals, with gumma formation."

Disease as a Factor in Evolution.

Long ago Lyell [14] laid down the important geological principle that changes in the past are best interpreted by similar processes seen at work in the present. Thus Osborn [2] points out how vast herds of wild buffalo were exterminated in South Africa between 1890 and 1893 by rinderpest, which also killed off almost completely the wildebeeste or gnu and the giraffe. Moreover, fly-borne diseases such as surra have been powerful agents in the destruction of the equidæ, just as the *Trypanosoma brucei*, carried by *Glossina morsitans*, causes the fatal nagana in domesticated horses and cattle. Several species of tsetse-flies of the genus glossina have been found by T. D. A. Cockerell [5] in a fossil state in the florissant shales of Colorado, which are of Oligocene (mid-Tertiary) age. Whether these flies could carry trypanosomes we do not know, but at this part of the tertiary period horses were evolving very rapidly, and epidemic forms of nagana might have had marked influence on their extinction or survival. It is curious that horses are found in America up to the end of the Tertiary period, but after that they disappear completely, and had to be reintroduced by man when the country was first colonised.[15]

Modern biologists and palæontologists lay great stress on persistence as a characteristic of the evolution of certain lineages. The most frequently quoted example of this is the brachiopod lingula, whose fossil shells are found in the ancient Cambrian deposits, and which yet has persisted through all the subsequent epochs, and lives to-day on the shores of our tropical seas. Its form has scarcely varied during these æons of time and has withstood all the stresses and strains of environmental change, while all its collaterals have perished, or spent themselves in varying to suit their changing circumstances. The modern exponent of evolutionary methods talks of an inherent persistence or invariability, in such a lineage, so that energy is not used up in starting new phylæ, but is only employed in carrying on the main stem. Lang [16] gives us his idea of one aspect of the evolutionary process, thus: "Our supposed primitive organism then, tense with potentiality, curbed by inhibition,

periodically breaking out as inhibition, is removed in bursts of evolution along similar and definite lines, is a very different creature from the passive organism of the orthodox Darwinian, which conveniently varies in all directions, and allows natural selection to determine the course of its evolution." It is true that Dr. Bather,[17] the eminent palæontologist of the Natural History Museum, South Kensington, has stated that Lang has gone too far in postulating such "an insistent tendency in living organisms, and by putting the environmental factor so much in the background." But those of us who are always coming in contact with pathological phenomena must realise that a powerful element in this struggle is the acquirement of, or failure to acquire, an immunity. Modern bacteriology has taught us that this does occur, and examples of it are seen in everyday life among man and animals.

The fall of classical Greece and the triumph of Alexander of Macedon is now believed by some [21] to have been largely due to the crippling of the inhabitants of that country by malaria. It has even been suggested that the invasion of Eastern Europe by the Turkish hordes in 1358 [22] was the result of the devastation and partial extinction of the populace in the previous few years by the Black Death or Plague; and we all know how cholera, measles, and syphilis have played similar parts in different areas. In the same way the large vertebrate fauna have been more or less decimated at times by rinderpest and other zymotic diseases. Osborn,[2] discussing the close parallel between the present fauna of Central Africa and that of North America in Tertiary times, says: "From these recent discoveries it appears that immunity from disease is one of the most important features of animal adaptation to environment, and that, conversely, non-immunity has probably been one of the most potent causes of diminution and extinction."

One cannot but feel certain that disease in its various manifestations has played a much greater part in the evolution of the different forms of life in this world than the biologists have ever realised.

PRISON BREAKERS.[1]

THERE is always something of psychological interest about prison breakers, for their deeds are committed by individuals who show that the impulse to infringe social barriers holds good when they find themselves confined in a material sense. The popular story of Jack Sheppard, when inquired into, seems to be really true; indeed, Harrison Ainsworth has hardly done justice to the ingenuity with which his hero escaped from Newgate; while Jack Sheppard's similarity in psychological make-up to Haggart, the famous Scotch prison breaker, is remarkable, for in each case these resourceful rogues appear to have been mainly led to crime through vanity. Perhaps more widely known than either as one for whom locks and bars have no terrors is Baron Trenck, and his exciting adventures form the longest essay in the book. Except perhaps Latude and Casanova, mention of whom the author omits because their exploits are over familiar, Trenck has the widest fame for prison-breaking, and his adventures are certainly better documented than those of Casanova. Mr. Philip has produced a very readable book.

A NEW MEDICAL JOURNAL IN INDIA.

WE have received a copy of the first issue of the *Si Medical Journal*, the quarterly production of the Si Medical Union, edited by Dr G. F. Rodrigues, who held number of resident appointments in London hospita ten years ago. The issue contains a series of short articl on keratodermia blenorrhagica, furunculosis of the fa cancer of the breast, and intussusception. The first-nam disease is one of the rarest in the whole of dermatologi literature and the case described is not very convincir The suggestion to treat scabies in man by the o administration of sulphur deserves a trial elsewhere, for cures are claimed. Apart from these scientific papers, number of highly controversial political matters are touch upon, and the editorial article makes no attempt to defi the policy of the journal. The publisher is Dr H. J. Wan at the Daily Gazette Press, Karachi. and the annual su scription (inland) Rs.2.0.0 and (foreign) Rs.2.8.0, post fr

HONOURS TO MENTAL NURSES.

IN our annotation on the New Year Honours whi appeared in THE LANCET of Jan. 7th (Pp. 35) while menti ing the appointment of Miss M. M. Thorburn, matron of t London County Mental Hospital, Horton, we omitted mention the name of Miss Jane Mottershead, senior assista matron to the Cheshire County Mental Hospital at Macc field, who was appointed to be a Member of the Civil Divisi of the Order of the British Empire. The mental nurse recei little enough recognition of her devoted service in a v exacting branch of the nursing profession, and it is peculia encouraging for her to find the value of her work recogni in this way. Among the Officers of the same Order appe the name of Mrs Isabel Brogden Carter, a member of Mental Deficiency Committee in the same county.

A BOOK OF DAYS.

IN "Roses, Marjoram and Nettles," (London: Meth and Co. Ltd. Pp. 388. 5*s.*) Miss Adelaide L. J. Gosset tried to give her readers glimpses into "the mysteri teeming life of long ago." She has selected men and wom belonging to almost every profession—authors, engine lawyers, generals, architects, statesmen, inventors—giv quotations which throw them and their work into rel Edward Jenner is amongst the few medical men includ with a quotation from Isaak Walton which runs: "Jen pleaded with Napoleon on behalf of some British prison and Napoleon was on the brink of refusing to release the when Josephine whispered the name of 'Jenner,' upon wh Napoleon said, 'There is nothing we can refuse that m Jenner was triumphant." Certain days are reserved recalling events such as the passing of the Bank Holi Act, the opening of the London docks, All Fool's Day, Founding of the Royal Society, the chartering of the Z logical Society of London. The quotations are extrem varied and many of them quite entertaining.

NEW PREPARATIONS.

Messrs. Burroughs Wellcome and Co., London, have s us "*Wellcome*" *Antipneumococcus Serum, Type I.* Ser protecting against infection with Pneumococcus, Type in laboratory tests is now widely used in the treatment pneumonia. Such a serum is prepared at the "Wellcom Physiological Research Laboratories. Antipneumococ serum is tested against cultures of pneumococci of s virulence that 0·000 001 c.cm. of an 18-hour culture will a mouse. A dose of 0·2 c.cm. of "Wellcome" brand A pneumococcus Serum, Type I., will protect a mouse agai 0·1 c.cm. of the culture—i.e., 100,000 fatal doses. It thus reasonable to expect favourable clinical resu "Wellcome" brand Antipneumococcus Serum, Type I. supplied in phials containing 25 c.cm.

Bismogenol, which is recommended for use in vari stages of syphilis, is prepared by Messrs. E. Tosse and of Hamburg, and imported by Messrs. Boxall, Smith Co., 163A, Strand, London, W.C. It is an example modern bismuth therapy, and contains 60 per cent. bismuth combined with oxybenzoic acid. The contributi to the German medical press on the non-toxicity successful action of the preparation are numerous, an good many of the reports either emanate from hospitals have been made to general or special medical societ The technique of the injection is the same as that for insoluble mercury salts; it is recommended that 1 c. should be injected every third, fourth, or fifth day into upper external quadrant of the gluteal muscle, up 25 injections being given, though the dose can be m larger without danger. It is stated in the medical obser tions that pain does not occur, so that if the syphil symptoms appear to the doctor to warrant a more dra course of administration there will not be any distress resistance from the patient.

THE temporary address of the National Association for Prevention of Tuberculosis is 1, Gordon-sq., London, W.C.

A Dissertation
ON
DAMAGES TO BONES AND REPUTATIONS.*

BY ERNEST W. HEY GROVES, M.S. LOND., F.R.C.S. ENG.,
PROFESSOR OF SURGERY, UNIVERSITY OF BRISTOL; SURGEON TO BRISTOL GENERAL HOSPITAL.

"Bones are supposed to be filled with red or yellow marrow; in reality they are full of black ingratitude."
C. B. LOCKWOOD.

THE advance of specialisation in medical practice has not yet taken the diagnosis and treatment of fractures out of the hands of the general practitioner. Although the majority of cases are eventually treated in hospital, yet a very large number must always be seen by doctors in general practice. And now that most country districts are provided with cottage hospitals every type of fracture may come there for diagnosis and treatment by medical men who must perforce undertake this responsibility.

Several causes have combined to make this responsibility more onerous in recent years. The general advance of surgical methods, in diagnosis and technique, the advent of radiography with the possibility of the layman being able to see the broken bone for himself, and the requirements of the Workmen's Compensation Acts are the chief of these causes. And always there looms the possible menace of civil litigation by or on behalf of a dissatisfied patient, in which it is sought to punish the doctor for alleged negligence or malpraxis. A fracture so often involves not only a damage to a bone, but to the reputation of the doctor, that it seems worth while to consider this subject and to discuss the kind of fracture which causes difficulties, the nature of the resulting disability, and, above all, how to seek the paths of safety for the patient and of security for the doctor.

ONE HUNDRED CONSECUTIVE CONSULTATION CASES.

I think it will make the consideration more practical if I give a summary of the last 100 cases in which my opinion has been sought at a long interval after the accident—that is to say, cases in which primary treatment has been carried out but has proved unsatisfactory. Here, then, are the bare figures of the cases classified in eight groups.

Humerus (excluding lower end)	7	Femur (shaft)	12
Elbow	15	Tibia and fibula (shafts)	22
Radius and ulna (shafts)	17	Ankle	11
Colles	7		
Hip (i.e., neck of femur)	9		100

This list somewhat surprised me in regard to two notable omissions—namely, fractures of the clavicle or of the knee-joint, that is of the lower end of the femur. I think that clavicle fractures are now treated very much better than they used to be, because it is recognised that mobility of the shoulder must be maintained, whilst restricting apparatus, other than slings, which support the arm and keep the shoulder back are superfluous. The knee fractures are not in this list for quite another reason, and that is that everybody, doctors and patients, are frightened of these injuries, and realising from the outset that they are likely to give bad results, they are sent direct to hospital or to a consultant. Whilst admitting the gravity of knee fractures I do not think that they ought to cause undue anxiety, as they readily yield to traction methods or to open operation. They certainly do not alarm me as much as the corresponding fractures of the elbow-joint.

Humerus (excluding the lower end).—There were seven of these cases, in four of which the upper end was fractured and in three the shaft. In fractures of the upper end, whether of the head, tuberosities or neck, the two points of importance are to make an accurate diagnosis by the X rays and to maintain the limb in full abduction until early union has taken place. X rays are necessary, not so much to make the diagnosis—although without them an impacted fracture may be overlooked—as to ascertain details of the shape and direction of the break, the presence of comminution or dislocation. If the head is dislocated and the neck broken then the open operation is the only reasonable treatment, but in all other cases traction in full abduction by means of a Thomas straight splint should be the first method tried, whilst impaction by open operation is used for cases not reduced by the abduction. All these shoulder fractures should be kept up in an abduction splint after reduction has been effected, and later on one of the light wire patterns which maintain a position of bent elbow, as high as the shoulder and hand nearly opposite the face. This is the best means of preventing stiff shoulder with atrophy of the deltoid, which is the usual disability following a badly treated case.

Of the fractures of the shaft, two were cases of non-union with false joints, and one was merely a condition of delayed union associated with defective plating. Of non-union of fractures of the humerus I will content myself with saying that I think the condition might often be prevented by putting up the arm in an ambulatory abduction splint which is the only way of securing immobilisation and preventing the drag of the arm. When once a false joint has been established nothing but a reconstructive operation is of any avail, and this operation is one of great difficulty, involving step cutting of the bone-ends and possibly bone-grafting.

Elbow.—The 15 cases included two fractures of the olecranon which had been overlooked, with subsequent stretching of the fibrous union and one a rare condition of loose bodies, one of which was certainly a broken off fragment of the articular end of the humerus. The remaining 12 were all the typical broken lower end of the humerus in children or young adults, which in all these cases resulted in a more or less stiff elbow, and in three led in addition to that most dreaded complication, ischæmic contracture.

From the point of view of guaranteeing a good functional result, I think the fractured elbow in a child is the most difficult case which a surgeon may be called upon to treat, whether he is a country doctor or an experienced specialist. The simplicity or complexity of the fracture of the humerus is no certain guide to prognosis. One of my patients who developed actual ankylosis had a simple separation of one condyle which united in perfect position. Two cases were put up in full flexion, three in moderate flexion, seven at right angles. This, so far as it goes, shows that the more flexion can be secured the less is the chance of a stiff elbow. Probably the most certain cause of stiffness of the elbow is injudicious massage and forced movement. The ideal treatment consists in reduction under an anæsthetic, flexion of the arm, and no forced movements. Only gentle massage is used, and the arm is left alone for a week, and after that is allowed to drop by its own weight once a day as far as it will without pain and then replaced in full flexion. Forced painful movements within a few days of the fracture, and deep massage, are responsible for most of the stiff elbows in which the reduction of the fracture has been complete. Open operation gives no assurance of success as far as the future mobility of the elbow is concerned. In regard to displacement, the best result will follow manipulative reduction, and open operation should only be used when manipulation has failed, and particularly when one of the condyles is displaced. Open operation should be of the simplest possible character, a mere impaction or fixation of a condyle by means of a fine steel nail. Elaborate plating or

* The substance of this paper was delivered in the form of two addresses, the first to the Wiltshire Division of the British Medical Association at Chippenham, and the second to the Newport Medical Society.

wiring may restore a good shape to the bone, but will almost certainly leave a stiff joint.

Ischæmic paralysis or, as it used to be called, Volkmann's contracture, is a tragedy both for the patient and the doctor. In a bad case the whole forearm becomes stunted in growth, the muscles atrophy to fibrous cords, and the fingers are contracted into a claw shape. In cases of moderate severity great amelioration can be effected by careful treatment, carried out for one or two years, but the patient usually remains more or less crippled. It is due to a blocking of the circulation, caused primarily by an effusion of blood, and sometimes secondarily by tight bandaging. At one time, when the condition was first described, it was thought that it only resulted from tight bandaging over narrow splints. We know now that it may also arise in cases which are not splinted at all, but only put up in acute flexion. In three cases of the present series all were manipulated under an anæsthetic. One was bandaged on to an angular splint, one was fixed by a plaster bandage, and one was bandaged in full flexion. The important practical points are the length of the time which has elapsed since the fracture, the degree of swelling, and, above all, the condition of the pulse. In all doubtful cases with much swelling and a pulse definitely smaller on the affected side, it is much wiser to do nothing more than lay the arm on a pillow with the elbow at a right angle until the swelling has gone down and the pulse has returned. I think that text-books are not explicit enough on this point—namely, that full flexion of the elbow can be just as dangerous as a tight bandage.

Fractures of the Radius and Ulna Shafts (17 cases).—In most of these cases (11) the serious trouble which called for consultation was the displacement of the shaft of the radius towards the ulna, so that the hand deviated towards the thumb and supination was lost. This sagging inwards of the radial fragment is very difficult to prevent, even if the case is seen within a few hours of the accident. I know of no splint or traction appliance which effectively controls the tendency of the radius to fall towards the ulna. Apart from operation, the one chance of success lies in very careful reduction under the guidance of the X ray screen. In this way the radial fragments can be made to impact, and then they will hold. If the case is seen a few days or more after the accident, and if then the lower radial fragment is inclined towards the ulna, it is much better to operate than to temporise further with splints or manipulation. Generally the operation is very simple, consisting in mere impaction of the radial fragments, using an intramedullary peg only when the impacted fragments refuse to remain in contact. After reduction and impaction of the fracture, the arm is put up with the elbow at right angles, midway between supination and pronation, or in full supination. Of the remaining cases in this group, five were fractures in which some form of operation had had a bad result, and in one there was non-union of the ulna. It will simplify this paper if I defer consideration of these for the present.

Colles's Fracture (7 cases).—In one of these the fracture had been compound, with severe sepsis. In all the remaining six, deformity with loss of function had resulted from incomplete reduction of the original displacement. This point is therefore one of great importance—if the displacement is really and fully reduced then there is comparatively little fear of a bad result. The cases likely to lead to trouble are those in which the deformity is not extreme, being hidden by swelling or disguised by splinting. In early cases there ought not to be any real difficulty in correcting the deformity under an anæsthetic. In later cases a wrench may be used. Of the six cases under present consideration, one gave a satisfactory result after late reduction (six weeks), one required an open reduction (two months after accident), and the remaining four either refused further treatment or were not considered suitable for such.

Neck of Femur (9 cases).—These were all fractures of the true neck of the femur, or, as they used to be called, "intracapsular." In one case the patient had never been laid up, but persistent pain required investigation, and the X rays revealed an impacted fracture six months after the injury. No special treatment was required at this stage, and apart from humiliation to the doctor and the risk of legal action no great harm was done. In one case the patient was a girl of 14, who became lame after a trivial accident and eight weeks later the X ray showed that the epiphysis of the head of the femur had slipped so as to cause well-marked coxa vara. This was corrected and pegged by an open operation, and a year later the form and function of the hip were perfect. All the other seven cases were instances of non-union after periods varying from a few months to two years. It is not sufficiently recognised that these fractures do not unite when left alone or when treated by a straight splint or by simple traction. If a fracture is through the neck of the femur well above the intertrocanteric line, it will never unite unless it is impacted either by the original accident or by artificial means. And, further, the fractures which appear to be impacted—i.e., are in good position with no displacement—are very likely to become disunited unless very special precautions are taken. Two of my cases were instances of this. In one the patient was a boy of 16, and the other a man of 55. In each it was taken for granted that the impacted fracture was united long before union had taken place, active and passive movements were encouraged and full massage employed, and in both the fracture became disunited and an operation was required. An impacted fracture of the femoral neck should be treated by fixed abduction for six weeks, and then walking calliper for six months, otherwise there is a big risk of coxa vara or non-union.

It should therefore be laid down as a definite rule that no fracture of the true neck of the femur will ever unite unless it is forcibly impacted and held in this impaction for at least six months. On the other hand, it is equally true that in the great majority of cases this treatment of impaction will bring about union. It is quite unjustifiable to abandon such a case to the misery of painful lameness, even if the patient is of advanced years. There are two effective methods of treatment. In one the leg is forcibly pulled down under an anæsthetic, and then forced into a position of full abduction and slight internal rotation so as to force the broken surfaces together. This position is maintained by a plaster case extending from the lower part of the chest to the foot. The application and after-care of such a plaster splint can only be undertaken by those accustomed to this work. But in all cases of patients of active habit and in good health, and especially when three months or more have elapsed since the accident, I think it much more satisfactory to bring about impaction and to fix it by means of an open operation, driving a bone peg through the neck of the femur. In the seven cases under present consideration only one was treated by plaster abduction, and that was a stout and alcoholic woman who refused operation. The result was fairly satisfactory, being a close fibrous union with some lameness, but no pain. The other six cases were all pegged, and in all bony union resulted. In one of these cases, a woman of 35, the non-union had persisted for two years; but, nevertheless, perfect union resulted from the operation so that a year after she could walk with neither pain nor lameness and the X rays show perfect restoration of the femoral neck.

Shaft of the Femur (12 cases).—In one of these the chief trouble was caused by sloughing of the skin over the foot and heel due to traction applied to the foot. In one a compound fracture had been plated with the usual result of sepsis, necrosis, and malunion. In six there was gross malunion with angulation and shortening, and in four there was non-union with pseudarthrosis or a fibrous joint. In two of the cases of non-union and in one of malunion the fracture had been treated by primary plating. In one of these the plate and screws had been removed

ecause of sinus-formation, and in the others the late and screws remained in position as loose foreign odies. Time and space do not permit of an adequate liscussion of this group of cases, and I must content nyself with laying down a few general principles.

First, as to the best method of securing good union f the femur—that is, a sound healing with full ength and good position. I am firmly convinced that he routine method should be that of adequate raction. It is not a question of using So-and-So's plint; but it does mean that the femur must be ulled upon by a traction force which will over-educe the displacement with half an inch or more o spare, and which can be relied upon to maintain his extension for at least four weeks. In some atients, including all children, this can be done by dhesive plaster and a Thomas splint. But in muscular dults, and especially when the case comes for treat-nent a week or more after the accident, pin-traction s much more satisfactory. It is less painful to the atient and much more certain in its results. Ice-tong allipers or transfixion pins will both give an efficient old on the bone, but I must confess I greatly prefer he transfixion pin. I do not hesitate to use as much s 60 lb. traction in those cases where there is much hortening and of old standing. The weight is applied y two pulley blocks. Directly the over-length has een obtained the weight is reduced to 40, 30, or 15 lb. he one crucial test of the efficiency of any traction ethod should be that the broken bone is really ulled out to a little more than its normal length ithin a few days of the application of the traction. nything short of this is inefficient and is likely to ive a poor result. But if this test is carried out, hen there may be perfect assurance that neither alunion nor non-union will result. Furthermore, the nion of the bone will be rapid and firm, much more than after the most perfect plating. In regard to ne treatment of the six cases of malunion, in three ases several years had elapsed since the fracture, ne bone had undergone reconstruction, and no opera-on was advised. In the other three osteotomy or e-fracture was done and the cases treated by pin-raction. In all these full length and good union as obtained. The four cases of non-union were all uccessfully treated by reconstructive operations. In ne, an oblique fracture, it was possible to refresh ne fracture and to unite by two Parham's bands. n the other three the bone-ends were reshaped and nited by means of a pair of bone plates bolted gether on either side of the fracture. In all these nion occurred, but the healing process was slow, aking 8 to 14 months before the bone was strong ough to bear the body-weight.

Shafts of the Tibia and Fibula (22 cases).—These are sily classified as follows:—

alunion	11	Delayed union	5
on-union	5	Compound fracture ..	1

nine of the cases of malunion there was marked gulation, which threw the ankle-joint out of line, using some degree of valgoid deformity. In the maining two cases where there was 1 or 1½ inches shortening but no angulation, the foot was affected, and therefore there was comparatively tle disability, and as a year or more had elapsed nce the accident in both these cases no further eatment except a slightly raised boot was advised. ought not to be difficult to put up a tibia so as to oid angulation. The mistake usually arises from e use of some type of box-splint or plaster-of-Paris which the true position of the bone is concealed. the radiogram shows marked over-riding, then uction should be undertaken without delay. Efficient uction can seldom be applied by adhesive plaster, d it is essential to use an ice-tongs calliper or a all pin through the os calcis. When full length or erlength has been secured, it is comparatively easy correct any angulation, and it is wise to keep the ot inverted and at a right angle all the time. Within veek of achieving a good position of the fracture, leg may be put in a plaster case which reaches from the balls of the toes to the tubercle of the tibia. The plaster is applied with the transfixion pin in position, full traction being maintained all the time, and the pin is only removed when the plaster is set. A week or two later the plaster is cut into two halves which are removed for daily massage. In the long spiral fracture, even efficient traction will often fail to make good reduction, and it is in such cases that open operation is strongly indicated and may be relied upon to give rapid union. From the point of view of simplicity and mechanical efficiency some form of cerclage is much more satisfactory than plating.

There were five cases of non-union, varying from one to four years after the accident. In no less than three of these a plating operation had been done, and the failure of such operation must be regarded as a definite cause of non-union. In the first place, there is a wide exposure of the bone and a partial stripping of its external vascular supply. Then, if plates and screws do not hold, these lie as loose foreign bodies across the fracture and prohibit callus union. When at last the plates and screws are taken out, the bone has usually become indolent, sclerosed, and incapable of healing. In these three cases (non-union after plating) the final treatment was by a massive graft taken from the opposite tibia and in all union resulted. Of the other two cases of non-union where the condition was due simply to want of apposition between the fragments, success was attained in one by refreshing and shaping the bone ends, impacting them together; but in the other case this treatment was followed by secondary hæmorrhage, necessitating amputation.

In five cases the trouble was merely that of delayed union. Any case of fractured tibia in which the fragments of bone are in good contact and alignment, but where union is slow, may be treated with perfect confidence by walking exercises. The leg is supported by a pair of short irons from the heel of the shoe to the tubercle of the tibia, and the patient encouraged to bear weight upon the foot. In all these five cases this treatment caused ultimate union, though very slowly. It is very important to bear in mind that if union does not occur in spite of good contact then there must be some underlying cause, vascular or cellular, and that this same cause will be very unfavourable for any open operation.

In one case the fracture had been compound and had been plated. Then sepsis had compelled the removal of the plate. The doctor suggested and the patient begged for amputation, but I am glad to say that long and patient traction with suitable toilette of the wound, and occasionally removal of sequestra, eventually led to a sound union and useful leg.

Ankle (11 cases).—In eight of these a bad result had followed incomplete reduction of the fracture. Valgoid deformity of the foot with a painful stiff ankle was the general result. As in the similar fracture at the wrist-joint the first and most important essential to success is full and complete reduction. This ought to be checked by radiography, because it is difficult to be certain of the relative position of the bones when they are covered by swollen soft parts. The foot must be brought forward, dorsiflexed, and inverted, and when this has been done a close scrutiny is taken of the bones by the X rays to see whether there is any splintering of the posterior surface of the tibia or fracturing of the calcaneum or astragalus or separation of the tibia from the fibula. In some cases I think that satisfactory reduction has actually been made by pulling the foot forward, and then this position is lost by the leg being placed on a padded back splint in which a slot is left for the heel and tendo Achillis. Into this slot the foot slips backwards. A very good and easy method is to place the leg and foot in a piece of stockinette, the upper end of which is fixed by adhesive plaster above the knee. The foot is pulled forward and wrenched into an over-corrected position and then suspended to the bars of a bed cradle, hanging the limb by the toe-piece of the

stocking in such a line as to preserve dorsiflexion and inversion.

In the eight actual cases of malunion under consideration, a fair degree of restoration of function was achieved in five by manipulation or by osteotomy. In one case (originally compound) amputation was advised. One refused treatment, and in one an open operation produced a result which was of doubtful benefit. In three cases of ankle fracture the bones had united in good position, but there had resulted in the one a stiff ankle and in two a dropped foot, with shortening of the tendo Achillis. In all these improvement was attained by wrenching under an anæsthetic or by lengthening of the tendon.

General Principles.

Before leaving this part of my subject I should like to emphasise a few general principles.

The importance of a critical examination of the fracture within a few days of its being put up.—It is, of course, essential to recognise the existence and nature of the fracture before treatment, but granting that this has been done, and treatment by splinting, posture, or traction carried out, then it is equally necessary to get absolute proof within the first week or ten days that the bones are in good contact and correct alignment. It is the failure to get this proof that underlies most cases of bad result. Typical cases are those of fracture of the upper end of the humerus, of the femur, or of the leg bones, where the patient is quite comfortable and to the superficial observer everything looks all right. But the arm comfortably bandaged against the chest or the leg slung up in a splint or perhaps encased in plaster really presents to the X rays gross malposition, and if this is discovered within the first week no very great harm has been done, because it is not too late to bring about correction; but it is wrong to wait for a month or six weeks because in this time malunion may occur or non-union may be established, and to cure either of these will not only require a much more difficult operation, but the patient has a just grievance, whilst the doctor is involved in discredit.

Danger of inefficient plating operations.—In 9 per cent. of the whole series, or about 17 per cent. of the fractures of the shafts of the long bones, the bad result followed from a plating operation in which the plate and screws failed to hold and had to be removed. In most of these there was no evidence of sepsis, and the plate had remained for a long period loose in the tissues, which had healed over it. Either the plate was too short to afford adequate internal splinting, or else external splinting had been neglected, and in either case the result was malunion or non-union. It is very unfortunate that so many practitioners still regard the plating of fractures as the method of choice in all cases where malposition persists. In the arm bones simple operation of impaction, followed by adequate splinting, or, in the leg bones, efficient traction, can be relied upon to give much better and more certain results than plating, and these methods are not only much easier but are devoid of the immediate and remote dangers which are involved by plating.

Dangers of plating compound fractures.—It would seem quite superfluous to say anything on this subject; yet open fractures are still being plated and lives and limbs endangered thereby. When a wounded man is brought in with a broken bone protruding through the skin or seen in the depth of a ragged wound, it would appear that this condition exercises an irresistible influence on some surgeons, who, in spite of all that has been said to the contrary, feel that they cannot be content with a wound toilet unless they also plate the bone. In the days of the war the operation was tried again and again, usually with disastrous results, and the method was killed by its own badness. In civil life any one medical man may be tempted once; if he yields to this temptation it is not likely he will do so a second time. But I would plead that he should not yield even this once, because if he does he will probably bring great danger upon his patient and great trouble to himself. Activ sepsis in the wound requiring the removal of the plat is the least of these dangers. Extensive necros causing shortening or non-union is the usual resul whilst other cases may end in amputation or deat The subtlety of the temptation lies in the fact tha every now and then the operative adventure of platin an open fracture succeeds, and the adventurer probabl publishes his case, perhaps attributing his succe to the use of some new antiseptic. But while a sing success is quite honestly published, 99 dismal failur go unrecorded. Any open fracture which can b safely plated should be converted into a close fracture and the soft parts soundly healed fir before the bone operation is undertaken. But in th great majority of the cases if efficient immobilisatio and traction has been carried out during the waitin period, good union will have occurred before the sa time for plating has arrived.

The essential simplicity of fracture treatment.—Th very essence of successful treatment lies, I believ in simplicity. The bones are displaced by the origin violence, by gravity, and by the pull of the muscle Efficient traction in the axis of the limb must be ma as the first and necessary act in reduction, and eve surgeon should be master of some such method efficient traction. This may be by adhesive applianc tied to fixed apparatus or by a mobile weight acti over a pulley and holding by means of an ice-to or transfixion pin. But the traction must be efficie as judged by the length of the limb, the radiograph appearance of reduction, and the permanence of t result. If this standard of efficiency is reached, th very few cases will require operative treatment, a I believe that the more experienced a man becom the fewer cases he will require to operate upo Certainty and celerity of recovery may justify open operation in some cases—e.g., an inward displaced shaft of the radius, a separated epicondy a fractured neck of the femur, a displaced femo condyle, a long spiral fracture of the tibia, or separated malleolous. In such cases usually t operation need only be of a very simple charact consisting in open reduction and impaction w occasional pegging or cerclage.

Fifty Consecutive Legal Cases.

The collection of reports of cases in which le proceedings have been threatened or action taken more difficult than that of my own consultations a therefore, I have had to be content with only Grouping the cases according to the bones involv we have the following list:—

Clavicle	1	Femur neck	1
Shoulder	9	Femur shaft	3
Elbow	3	Patella	1
Radius and ulna	4	Tibia	5
Wrist	5	Ankle	5
Digits	3		

Clavicle.—The accident and the injury were o straightforward character, and no doubt existed as to the diagnosis. For this reason no radiograms d been taken. The case passed into the hands of another practitioner, who considered that there was evidence of pressure upon the brachial plexus b a deep splinter of bone. He operated upon the fract and united the bone by means of a plate. The doc who first saw the case was sued for negligence, it was useless for him to protest that there had b no evidence of comminution or of special displacem of the bone, because he had no radiograms at his disposal.

Shoulder (9 cases).—In all of these there exis either dislocation of the joint or fracture of the head or neck of the humerus. In all of them X examination had not been made or had been dela for some weeks. In three cases dislocations had b missed; in four a fracture dislocation had b missed; in one a fracture had been missed, an one a fracture had been correctly diagnosed bu dislocation missed. This short and sad recital ha

requires a commentary, but it is certainly remarkable that the very same kind of case which many years ago first established the medico-legal importance of X rays should still furnish about 18 per cent. of the present list.

Elbow (3 cases).—Here again the trouble arose in all three cases owing to the absence of radiographic examination. In one there was a dislocation of the elbow which had been reduced, but a stiff joint followed, and at a later period X rays showed that whilst antero-posterior displacement had been corrected yet lateral dislocation had persisted. In one case a fracture of the lower end of the humerus had been missed, whilst in the third a fracture had been correctly diagnosed and treated but a coincident dislocation (of the head of the radius) missed.†

Radius and Ulna (4 cases).—In all these the absence of radiological examination was the cause of litigat on. In two the fractures were missed, and in the other two malunion and non-union occurred, and it was suggested that these complications might have been avoided if the character of the fracture and the position of the fragments had been subjected to inspection by the X rays.

Wrist (5 cases).—In one of these, a Colles's fracture in an elderly patient, a stiff and painful joint resulted, and a second practitioner to whom the patient resorted made certain unguarded remarks about its being "a bad result." Fortunately radiograms had been taken, and treatment carried out on ordinary lines, and therefore the threatened action was withdrawn. In the other four cases no X ray examination had been made. In one the fracture (impacted) had been missed, and in the other three. diagnosed as a Colles's fracture, some complication had been overlooked. This complication in two cases was a fractured scaphoid, and in one case a dislocated semilunar bone.

Digits (3 cases).—In all of these the main injury was so obvious that X ray examination was considered unnecessary. Two were dislocations of the thumb, one being compound and the other a severe laceration, in all three stiff joints followed, and a late radiogram showed splintering of the metacarpals or phalanges.

Femur (11 cases).—This is the largest group of legal cases, being 22 per cent. of the total. In every one without exception the alleged negligence consisted in the failure to make a diagnosis owing to the absence of X ray examination. In three of these impaction had occurred, and the treatment and after-result would not have been much affected by radiography. In one the patient had osteo-arthritis of the hip, which was made much worse by the accident, and it was not until four years later that the presence of the fracture was detected. The other seven cases suffered all the disability which attends an ununited fracture. This is the type of case in which there is perhaps the most excuse to be made for the neglect of X rays. In the first place the deformity is trivial, and no great disability, apart from pain, is apparent so long as the patient remains in bed. An X ray examination would involve the use of a portable apparatus which is often not available or a transport of the patient by stretcher or ambulance to a more or less distant hospital. So the dangerous policy of drifting along without a more accurate diagnosis than those of "sprain" or "contusion" is followed, and eventually the real cause of the disability is discovered, and only too often litigation ensues. Every case of hip injury in which pain and disability do not clear up within one or two weeks should be provisionally diagnosed and treated as a case of fracture, and the patient or her friends should be told of this. The necessary trouble and expense of the X ray examination will be then readily undertaken.

Femur (*shaft*) (3 cases).—In all of these there was malunion and shortening. In two no radiograms had been taken as the diagnosis was so obvious. In one case the patient was transferred to another practitioner, who was able to correct the malposition.

Patella (1 case).—This, like the solitary clavicle case, is of exceptional character and interest.

Dr. A saw a middle-aged lady after she had fallen on her knee and found her suffering from marked synovitis and effusion. This quickly subsided with rest and lotion, and the patella was felt to be of normal outline and mobility. The question of an X ray examination was discussed, but the doctor said he thought it was unnecessary, and as the patient was of very moderate means, but above the hospital class, she was very glad to avoid the expense. A few weeks later, whilst she was walking in the street, she fell down and had to be carried home. A local bonesetter was called to see her, and found an obvious fracture of the patella, with typical separation of the fragments. He advised calling in a surgeon, Mr. B, who operated upon the knee and gave it as his opinion that the patella had been fractured at the time of the first accident and that it ought to have been operated upon at that time. A good defence might have been made on the grounds that even if a fracture had existed after the first accident, yet as the fragments were not separated no operation was then indicated. But Dr. A's statement as to the condition of the patella could not be corroborated in the absence of X ray evidence, and as the claim was made for a comparatively small amount, the chief item being Mr. B's operation fee, it was paid without going into court.

Tibia (5 cases).—In two of these there had been no radiogram. The fractures were compound and the diagnosis obvious. But grave malunion occurred in each, due to lateral displacement which ought to have been recognised and corrected. In one case X rays had been taken, but had missed the seat of fracture. In the other two non-union occurred which required an open operation. But as in both these cases radiograms had been taken and ordinary splint treatment carried out, the threatened litigation had been dropped.

Ankle (5 cases).—In only one of these had X rays been used, and in this case they proved most fortunate, because subsequent trouble was caused by the action and statement of a bonesetter, who declared that he had "replaced one of the small bones of the foot." The radiogram produced proved the fallacy of this statement, and the threat of litigation was withdrawn. In all other four cases there had been no X ray examination in the first place—three "obvious cases of Pott's fracture," and one of "sprained ankle." In the latter a fracture of the malleolous had been missed, and in the former some complication—e.g., fracture of the astragalus, fracture of the scaphoid, or separation of the tibio-fibular junction.

Some Conclusions.

I feel almost ashamed of the wearisome reiteration which this account of the legal cases has involved. I confess that I had no idea when I began compiling this list of what were to be the special points revealed by it. I had no intention of specially advocating the use of X rays, and I certainly had no desire to push the wares of the radiologist. This I will make clear presently by saying what he will probably find unacceptable. But first I must point out the striking fact that in no less than 90 per cent. of all cases in which litigation resulted from the treatment of fractures, the main point on which a charge of negligence was based consisted in the absence of X ray examination. And yet there are many medical men to-day who will argue for and even practise an abstention from X ray examination on the grounds that they are quite capable of making a diagnosis without it! The question, however, is not always one of finding or missing the fracture. In one-third of the cases a correct diagnosis of the main fracture had been made, but the existence of some complication or malunion had been missed. And again it has happened twice in 50 cases that in the absence of X ray evidence an unfortunate doctor was at the mercy of another practitioner who subsequently operated upon the case. The actual analysis of the X ray cases is as follows:—

Diagnosis of fracture missed	28 (56%)
Malunion not recognised	6 (12%)
Some complicating injury to bone or joint missed ..	9 (18%)
Allegation by another practitioner, could not be refuted	2 (4%)
Total	45 (90%)

† This paper was written before the Tyndal *v.* Alcock case had been heard.

It seems to me that to make a diagnosis of a bone or joint injury without the X rays is rather like diagnosing cardiac disease without a stethoscope. It can be done sometimes, and in an age before the apparatus was invented it had to be done; but it was guesswork as compared with precision. There was a time when gynæcological diagnosis had to be made without vaginal examination, and a catheter passed for the female without removing the bedclothes, but now we know that it is much better to "look and see" than to "fumble and guess," and so it is in the matter of fractures and the X rays, and certainly the general public, judges, and juries are fully aware of the fact.

A very real difficulty does, however, exist in small towns, villages, and country districts in dealing with injuries which keep the patient bedridden, and particularly when the patient has only moderate means. Efficient portable X ray plant ought to be available wherever it may be needed, and it could be taken about by the ambulance service. The chief difficulty exists in the matter of personnel. It ought to be possible to have a technical expert, not a qualified doctor, in charge of such X ray plant who would work under the direction of a qualified radiologist, exactly as is done at every large hospital. In this way when a patient cannot afford a consultant's fee an X ray examination could be obtained at a moderate cost.

An exact analogy for this procedure exists in the kindred subject of pathological examinations. Sputum, urine, or tumours are sent by the doctor to a clinical investigation laboratory, and a report obtained for from 2*s*. 6*d*. to 10*s*. 6*d*. Probably the ultimate development of this idea of a cheap mobile X ray outfit will require some form of subsidy by the county health authorities.

Adverse Criticism.

Quite apart from this X ray problem, there remains about 10 per cent. of these legal cases in which the chief factor which menaces the medical man's peace of mind and reputation is the accusation or condemnation pronounced against him by another practitioner. Sometimes this accusing colleague is a man of no professional standing, who has nothing to lose and everything to gain by posing before the public as one who is prepared to point out and correct other people's mistakes. But too often he is a man of position, who in an unguarded moment allowed himself to criticise his colleague's conduct without having had any opportunity of hearing that colleague's statement of the case. Having once made this pronouncement he is forced to abide by it, and to fortify it at a later stage when the matter becomes one for litigation. There may be occasions when it becomes the duty of one medical man to make adverse criticisms of another practitioner's diagnosis and treatment, but it surely ought to be regarded as a rule of medical ethics never to make such a criticism without first inviting the accused colleague to some form of written or verbal consultation. Against this menace of an unscrupulous or indiscreet colleague I fear there never can be any protection beyond that afforded by the defence societies. These may guard our pockets, but they cannot ensure either our reputations or our peace of mind.

It is a part of the onerous responsibility of our calling that we have to face dangers and "to suffer the slings and arrows of outrageous fortune." The man who treats fractures must be prepared to risk this every day. He should be no more deterred from pursuing this branch of his work by the menace of ungrateful patients, or unmerited litigation, than the abdominal surgeon should be by the danger he runs of maiming his hands or losing his life by the prick of an infected needle. It ought, I think, to be a matter of consolation to us on those rare occasions when we meet ingratitude and unjust accusation to reflect how many times we really have deserved censure, but have instead received unmerited gratitude.

An Address

ON THE

RELATIONS OF THE

PUBLIC HEALTH SERVICE AND THE PRIVATE PRACTITIONER.

Delivered before the Manchester Medico-Ethical Society

By FREDERICK E. WYNNE, M.B. Dub., D.P.H.,

PROFESSOR OF PUBLIC HEALTH IN THE UNIVERSITY OF SHEFFIELD, AND MEDICAL OFFICER OF HEALTH FOR SHEFFIELD.

THE subject of this lecture appealed to me because my professional life has been divided almost equally between the experience of a general practitioner and that of a whole-time medical officer of health. Without the former experience, or most of it, I should have found it impossible to fulfil the functions of my official position with any measure of success. Even though he may have no direct clinical functions (though no member of the public health service can be completely divorced from such functions), it is essential that the administrator of municipal medical services should have an intimate knowledge of the outlook, the difficulties, and the ultimate value to the public of the private practitioner. The period over which my professional memory extends has witnessed an extraordinary development in our conception, not only of medicine and surgery in the purely scientific and technical sense, but in the relations of members of the profession to each other and to the public. After the academic calm of the university and some resident hospital appointments, my first experience of the rough and tumble of general practice was as assistant to a practitioner in a colliery district of Nottinghamshire. It sounds a terrible confession, but this was in the last century. My principal was totally ignorant of what was then modern medicine and surgery; he was also brutal, mannerless, and avaricious. My colleague was an "unqualified assistant" who told me that he had adopted the medical career after an apprenticeship to the "walking-stick and umbrella trade." He did all the midwifery; and the patients loved him. In fact, several victims of puerperal sepsis would have liked to have had his name on their tombstones. He was a nice little man, and when I got the sack, after a somewhat acute difference of opinion with my principal, he urged me to "go into business on my own" and, above all, to develop "a clap and pox connexion." These reminiscences illustrate some of the conditions of private practice in industrial districts in those days. My colleague must have been one of the last of the "unqualified assistants," but he was a much better "doctor" than his so-called "principal." He had sympathy and imagination, and I fear he must have been reduced to "travelling" in drugs or disinfectants. In those days, and for some years afterwards, at all events in working-class practice, doctors in the same districts were not colleagues. They were "opponents," not merely technically but actually. The only good mark I ever earned as an assistant was when I most unprofessionally, but quite unconsciously, "pinched" the patient of one of my principal's "opponents." She was the wife of the principal butcher in the village, and therefore very important. My self-esteem was greatly flattered, and it was only afterwards I learned that their usual attendant had been abandoned because his debit for joints and sausages had long since ceased to balance his contra-account for bottles of medicine. I might add that in that particular practice midwifery fees had been reduced to 9*s*., and there was a "private club" organised by my principal who contracted to attend whole families for 3*s*. 6*d*. a year! This was, of course, the "reductio ad absurdum" of "general practice," and resulted in atrocities to

which no normally constituted doctor could endure to be a party.

The New Spirit in Medical Practice.

It was some years afterwards in Leigh that I first witnessed the breathing of the new spirit, when "opponents" became colleagues, when we formed a medical society, which very soon amalgamated with the Wigan Medical Guild, and subsequently became the Wigan and Leigh Division of the British Medical Association, which I had the honour of representing for some seven years at the representative meeting of the Association.

Medical practice of the type I refer to was in those days a very sordid form of shopkeeping, a ruthless scramble for patients on terms that rendered them, even from the commercial point of view, unremunerative, and made the doctor's claim to professional status simply farcical. Any of the younger generation who would take the trouble to look up the files of the *British Medical Journal* and read the articles and correspondence on the subject of "contract practice," even in the early years of the present century, would obtain an insight into the conditions under which his father or uncles practised which would be a startling revelation, and I hope would enable him to appreciate the fate from which the British Medical Association has saved him.

National Health Insurance and the Mischievous "Eight-Ounce Bottle."

The reconstitution of the Association was decided at the historic Cheltenham meeting in 1903, when the Representative Body was formed, and by 1911 it was strong enough to fight, and very greatly to modify, what is now the National Health Insurance Act. Had the Bill gone through in its original form it would have meant the enslavement of the profession and a perpetuation of the very conditions I have described, the recognition of which was the real "vis a tergo" that forced the popular demand for reform in the medical treatment of the wage-earning classes of the community. But I think it is now admitted that with all its faults the Act has raised the standard of medical practice of this class and improved the status of the doctor. Personally I think the main objection to it is that it has failed to free the doctor from the tyranny of the "bottle of medicine" habit. It has done nothing to educate the public in this respect, and the panel doctor who does not prescribe or dispense a bottle of medicine will find his list of insured patients dwindling, as certainly as I found my private practice evaporating when I tried to educate my patients to abandon this particular form of vice. Unfortunately, we are now spending some three-quarters of a million pounds annually on "drugs and appliances" under the Insurance Act, and I am convinced that probably half a million of that amount is waste, and much of it mischievous. I expect our ancestors who resorted to universal bleeding did more good and less harm to their patients than we do by encouraging or maintaining the superstition whose outward and visible sign is the eight-ounce bottle.

Team-work in Medical Practice.

There are other factors which tend profoundly to modify the conditions of private practice, and one of them is our modern and inevitable dependence on the pathological laboratory for diagnosis. It is a development of this that causes many of the well-to-do classes to resort to places where they obtain not only diagnosis but treatment, not from a doctor, as of yore, but from a team of specialists. It is quite certain that as this form of medical treatment becomes fashionable for the wealthy its provision, more or less at the public expense, will be demanded by and for the poorer classes of the community. In fact, already some of our voluntary hospitals are being reorganised more or less on these lines. Already we have hospitals with a "surgical section" presided over by a chief who coördinates the work of a "team" of specialists, and is paid a salary for doing so.

In the meantime the health services organised by the State through the local authorities have undergone an enormous change, and in a direction which causes them to encroach more and more on the sphere of the private practitioner and the consultant.

The result of the "industrial revolution" was to create unheard-of wealth, and an enormous increase of population. What had been mainly an agricultural population distributed over the country and dependent on villages and country towns for markets and crafts suddenly underwent a process of clotting. Industrial towns grew up like foul weeds. The demand for cheap labour, and even child-labour, was inexhaustible. Anyone who owned a few square yards of land in the neighbourhood of any industry built a house on it. There were no restrictions on the exploitation of poverty by wealth. People prated about the "sanctity of human life" well knowing that men, women, and children were much cheaper than turnips, and a crop that raised itself without any trouble to anybody else. By the middle of the nineteenth century conditions had become so appalling and death-rates so alarming that the nation awoke to the necessity of taking this problem seriously in hand.

Public Health Legislation Following the Industrial Revolution.

The great Lord Shaftesbury had already won his battle over the first Factory Act and had at least emancipated infancy from one of the most ghastly forms of slavery. Chadwick began to preach sanitation, and the Towns Improvement Clauses Act was passed in 1847. It was the forerunner of much public health legislation. In 1870 the Education Act was passed, and five years later a great deal of scrappy public health legislation was consolidated in the great Public Health Act of 1875. Unfortunately, by that time the mischief was done. We had created a mess which we have by no means cleared up yet. The Act of 1875 very naturally and properly dealt almost altogether with the *environment* of the people. Only in the case of "dangerous infectious disease" was the individual considered, and even then he was not considered as an individual but as a possible danger to the rest of the community. It enabled, and in fact compelled, local authorities to provide adequate water-supplies, to make and cleanse roads and streets, to compel the "abatement of nuisances," and to make at least a beginning of clearing up the Augean stables bequeathed to us by the "industrial revolution." It was followed by a bewildering mass of legislation, various amending Acts, the Food and Drugs Acts, new Factory Acts, Acts dealing with the Notification and Prevention of Infectious Diseases, and all the housing legislation that began with the Act of 1890. There was a flood of legislation, and Parliament even concerned itself with details of the conditions under which rag flock was produced and handled!

Activity in the Twentieth Century.

At the end of the century the work was certainly not half done. We may perhaps claim that it was "well begun," but we can certainly claim no more. Nevertheless, with the beginning of the present century a very marked change came over the spirit of the public health movement, and the public demanded that the municipalities should turn their attention more and more to the direct care of the individual. By that time the campaign against tuberculosis had been in existence for a considerable number of years, but the problem of the infantile mortality-rate had not been seriously tackled, and this mortality had not at all followed the general mortality-rate in its downward career. It was not until the beginning of the century that child welfare work was generally established on the lines with which we are now so familiar, which have resulted in so startling a reduction in infant mortality. Its

proper corollary, the study and care of prenatal conditions, is the most recent growth of public activities. It is since the war that the public conscience has been aroused to the terrible havoc that was being wrought in the present generation and the threat to the future of the race involved in the prevalence of venereal disease. The control of these diseases also has been "municipalised" mainly, I regret to say, on a curative and not on a preventive basis. Again, it was towards the close of the first decade of the century that the Education (Administrative Provisions) Act was passed which established the school medical service, with all its enormous influence for good. Of course, our environmental work has not been neglected. Enormous arrears in the matter of housing have had to be overtaken at a time when the financial burden of the nation is greater than anything ever contemplated by our forefathers, and it should be remembered that in this matter of housing we are doing much more than overtaking arrears. We are aiming at a standard of health and amenity that would have seemed not merely Utopian but insane to the makers of the industrial revolution. We limit our municipal housing schemes to 12 houses per acre, and in some cases we are displacing people from slums where houses are huddled together at the rate of 200 per acre! Every civilised community is now rapidly eliminating such abominable relics of the Middle Ages as the "conservancy" system of disposal of excreta, while we are insisting that backyards shall be paved and existing houses maintained in a state of reasonable repair. Nevertheless, it is quite true, as Sir George Newman said some six years ago, that the centre of gravity of public health administration has shifted from the environment towards the individual, and in this shifting I think there has sometimes been a tendency to concentrate on the cure of end-results at the cost of prevention. Recent results in our antituberculosis campaign have been most remarkable, but in the early enthusiasm for "sanatorium" treatment in elaborate and costly institutions there was an enormous expenditure of public funds without any commensurate result. Education and rational preventive measures would in time make many of our venereal disease clinics an anachronism. Our failure to eliminate rickets is due not to want of knowledge of its cause or of the methods of prevention, but to our inability to get this knowledge home to the very class of people who most require it.

Effect of Public Health Enterprise on Private Practice.

In the meantime all this public work has made the most terrible inroads on the work and the earning capacity of the private practitioner. He has very largely lost his attendance on the expectant mother, and his maternity practice is now largely in the hands of highly qualified midwives. He has lost the infants and the school-children; the tuberculous and the sufferers from venereal disease. There is now a tendency, which becomes more marked every year, to demand the isolation, and therefore the municipalisation, of pneumonia, of measles, and of whooping-cough. Very soon we may acquire some accurate knowledge of the causes of that enormous group of more or less crippling conditions now lumped together in the meaningless mediæval category of "rheumatism," and still absurdly classified in the "international list" as "diseases of the organs of locomotion"! Some of these, if not all of them, will certainly come to be regarded as "preventable diseases," and to that extent the doctor's purse will again be depleted.

A deep resentment against this encroachment on the part of men who have gone through an arduous and expensive training seems to me quite natural, but not necessarily wise. As we have seen, the conditions of medical practice have changed. The majority of members of the public still want their own doctor, who "knows their constitution." They want his friendly manner, his sympathy, and, above all, his bottle of medicine—if possible," the same as they had last time." With the possible exceptio of the bottle of medicine, all these are good thing and I daresay when my time comes I shall welcom the presence at my bedside of the successor c Trollope's Dr. Fillgrave, without whose sanction n one could die respectably. But the custodians c the people, their politicians, the insurance companie and the so-called "friendly societies" will not, they can help it, permit the perpetuation of thes luxuries. The statesman sees that under moder conditions the nation can no longer afford avoidab invalidity, even though the medical profession ma still have a vested interest in disease.

It is useless for us to protest against these economi tendencies or to attempt to oppose them. I believ that with the lessened incidence of disease, and th increase of "team work" in the profession, th nation will not be able in future to support as man doctors as it has done in the past, and that we shoul endeavour to limit the entries of medical students b demanding a much higher standard of preliminar general education than we have done in the past. think that some experience of "general practice should be compulsory before any form of specialisatic is permitted, and that the profession should at lea try to reorganise itself from within so as to giv every member an interest in the preventive side of h work. In Sheffield, since I have been responsib for it, the clinical part of our prenatal and chil welfare work has been carried out entirely by a sta of general practitioners working on a part-time basi and, judging by our results and the smoothness of th administrative working, I see no reason to wish t change it. Our venereal disease clinics are operate by part-time specialists, and I think the future preventive work may, if they choose, be largely i the hands of private practitioners, provided they a prepared to maintain the value of public work b the standard of their private practice.

UNRECOGNISED TOXIC SUBSTANCES I HUMAN FÆCES.*

By DOUGLAS CHALMERS WATSON M.D., F.R.C.P. Edin.,
PHYSICIAN TO THE ROYAL INFIRMARY, EDINBURGH.

With an Account of Experiments by

P. DE, M.B., B.Sc. Calcutta,
ASSISTANT PROFESSOR OF PHARMACOLOGY, SCHOOL OF TROPICAL MEDICINE, CALCUTTA.

This communication is intended to be frank provocative and suggestive; to provoke thoug and commentary from teachers of clinical medici on the correctness of the views expressed, a to suggest to practitioners the necessity in t interests of medical progress of their independe thought and observation on facts which come dai under their own notice. The late Sir James Macken divided clinicians into two groups—those who do n know, and know that they do not know, and tho who do not know, and do not know that they do n know. I write frankly as a member of the first grou Stated shortly, my thesis is: the urgent necessi at the present time of clinicians directing th attention to the teaching of Bouchard, Metchniko Arbuthnot Lane, and William Hunter. Few will de the present unsatisfactory state of our knowledge the ætiology of most common medical disorders th fill our hospital wards to-day, our comparative hel lessness in curing them, or our too limited endeavo along lines of preventive treatment. Much attenti has been directed for many years, and with mark success, to making more complete our knowledge the physical signs of disease, to refinement in diagnos and to research work, both clinical and laborato dealing with the end-products of disease. Too lit

* A paper read at the Medico-Chirurgical Society Edinburgh on Jan. 18th.

ttention has been directed to the search for any ndamental principles at work in inducing the iseased states, the recognition of which would simplify nd clarify our present elaborate classification of iseases and would pave the way for a more rational nd successful therapy. My observations, over a period f nearly 30 years, have led me to think that the eaching of the above authorities, to which little erious attention is now directed by clinicians, rnishes a key both to the simplification of the present lassification of disease and to much greater success n its treatment.

Bouchard, Metchnikoff, Arbuthnot Lane, William Hunter.

Bouchard directed his attention to the problem of he toxicity of the urine and fæces, and its significance n relation to the æviology of various diseases. In mphasising as he did the influence of the liver and ile in controlling the abnormal fermentative and utrefactive processes, of which he found evidence n the fæces, he was in agreement with the views of any distinguished medical writers in the past who rrived at the same conclusion on purely clinical rounds. Bouchard's work on Auto-intoxication was ublished over 35 years ago; the great value and gnificance of much of his work has not yet been dequately recognised. Metchnikoff, approaching the ubject from the wide standpoint of a biologist of the oremost rank, made an extensive study of nutrition nd degeneration as seen in lower plant and animal fe. The results of his researches led him to the nclusion that a slow and insidious absorption of oisons from the large intestine was a factor of rimary importance in inducing the degenerative and clerotic changes characteristic of most common iseases in man. His conclusions, if established, are far-reaching importance. Little attention has so r been directed towards proving or disproving their alue. Arbuthnot Lane, from an independent clinical udy of the problems, is in general agreement with etchnikoff's teaching as to the profound importance the large intestine as the main source of origin of iseases. It is probably not too much to say that s powerful advocacy of his well-known views is owly exerting a marked influence on many thoughtful nd open-minded members of the profession. Opinions n the value of Arbuthnot Lane's teaching are, owever, strangely divided. On the one hand, we find ir William Milligan, in a preface to a recently ublished useful book on Chronic Constipation written y a layman, writing as follows:—

"Dedicated as the work is to that distinguished Surgeon nd Founder of the New Health Society, Sir Arbuthnot ane, to whose untiring efforts in the cause of Health the ublic owe so much, the part played by the author in resenting so much valuable information should not be llowed to pass without due acknowledgment and gratitude."

On the other hand, it would appear from Sir Thomas ordor's MacAlister lecture on Diet and Dietists that is commendation is another "glaring instance of ualified practitioners giving 'cover' to unqualified en." The time seems ripe for the profession to etermine in which direction the line of progress lies. he work of William Hunter should also be referred o. Associated as his name so honourably is with ork of great value on the anæmias, it is not commonly cognised thau his pioneer researches have far-aching significance and value in a much wider field clinical medicine. His work on the rôle of auto-fection from the intestinal tract, secondary to oral psis, brings it into close relation with the foregoing. n a recent appreciative reference to Hunter's work nd the scanty recognition it has received from the ofession, Sir Berkeley Moynihan, speaking of the position originally offered to Lister's epoch-making searches, submitted as an explanation that "some inds are impervious to novelty; truth seemed to be nt at an angle as it entered the rather denser medium their minds." In this connexion it might be added at the great significance and value to clinical medicine of Moynihan's brilliant contributions to surgery have so far not yet received the thoughtful consideration that is due. It is only right to add that in some of the special departments of medicine increasing importance has been attached in recent years to the probable rôle of an alimentary toxæmia in inducing various common disorders. A reference to several modern text-books on dermatology and ophthalmology, for instance, shows that many specialists in these departments of medicine are satisfied on general clinical grounds that some derangement of the bowel, of a nature not yet ascertained, is primarily responsible for some of the common diseases coming under their observation. This emphasises the necessity of the subject receiving more attention at the hands of the general physician.

Erroneous Teaching re Normal Fæces.

It would appear from the literature that the chief difficulty in the way of leading medical writers recognising the importance of what may, for want of a better term, be called alimentary toxæmia, lies in the "absence of proof." No one has adduced any exact experimental evidence that the fæces contain a substance or substances which can be proved by laboratory tests to exert a toxic action. Neither has any laboratory worker been able to produce a substance in a test-tube and say "Here is the toxic substance." On a question that is so largely clinical it is doubtful how far these criticisms have the validity claimed for them, but in any event their discussion is hardly necessary, and for this reason. The chief factor, which has arrested progress of our knowledge of the subject for so many years, is the profoundly erroneous views held by clinical teachers in general as to the condition of the fæces in health. The fæces of a healthy adult man on a judiciously planned mixed dietary are, like those of many of the lower animals, practically odourless; they show little or no sign of abnormal fermentation or putrefaction. The unpleasant odour which results from the administration of a liver pill, followed by a saline, should not be regarded as indicating that under normal conditions putrefactive changes of a gross nature are physiological. It should rather be interpreted as an all-important indication of the special importance of the liver and bile function in regulating the processes of primary digestion; it is possible that it should be interpreted as indicating that the judiciously planned mixed dietary referred to above, though excellent for all practical purposes, is not so physiologically perfect as it might be. A clinically accurate method of determining whether a bowel is reasonably clean or not is effected by the use of the enema syringe. In health, if the bowel is washed out by an enema of plain water, two and a half pints or thereby, the fluid will be immediately returned with the contents of the lower colon; if a second wash-out of the same amount be then given the fluid will be returned and it has the following characteristics: it will be practically clear, or of a light straw colour, it will be entirely free from odour, there is no deposit, or, at most, fragmentary traces of fæcal matter and mucus, are present; if a drop of the fluid is stained by Gram's method very few, if any, bacteria are observed. This condition of affairs is very rarely seen in hospital practice. On the contrary, it is no exaggeration to say that in probably 99 out of 100 ordinary hospital patients the second wash-out from the bowel is, on admission, a highly feculent, offensive excretion, dark brown in colour, with a copious fæcal deposit, and a Gram-stained film of a drop of the fluid presents a picture, which in regard to the number of bacteria present, is often indistinguishable from that of the first wash-out. This fact is itself conclusive evidence that, apart from any qualitative changes in the flora, there is an enormous increase of bacterial activity in the bowel, with great potential power of injury to the tissues. (In regard to the presence of bacteria in the fæces it may be stated that the writer showed conclusively some years ago that the traditional teaching as to the

vast majority of bacteria in the fæces being dead is erroneous.) This highly putrefactive state of the bowel is so universal in hospital patients that it has misled both medical men and nurses as to the normal. An illustration of the error into which clinical teachers have fallen on this subject may be quoted. Writing on the subject of the possible relations of Alimentary Toxæmias to Migraine, Dr. Hurst says :—

"We have never found any abnormality by means of test-meals, microscopical, chemical, and bacteriological examination of the stools and urine, radiological examination of the alimentary tract, lævulose test for hepatic inefficiency, estimation of blood-sugar, urea, uric acid, blood counts, and cutaneous tests for protein sensitisation."

This provides at once a good example of the thoroughness and inefficacy of some modern methods of investigation. No reference is made to the general appearance and highly offensive nature of the stool which would be amply proved if the test outlined above were applied. In a considerable experience of such cases I can confidently affirm that if the practitioner makes sound use of his unaided senses the more elaborate tests referred to above may, as a rule, be disregarded. And it is of practical moment to know that there is a most important relationship between the time required to restore the bowel to a natural state of cleanliness and the duration of the symptoms of the disease.

FIG. 1.

Toxins in Human Fæces.

If the teaching of the above writers is correct, it is reasonable to expect that modern methods of laboratory investigation should reveal conclusive evidence in its favour. In recent months I have had an opportunity of testing this. I was interested to learn some months ago that Dr. P. De, who had attached himself to my ward and laboratory for the study of some of the problems referred to in this paper, had devoted himself to the investigation of pharmacological problems in the Pharmacological Department of Edinburgh University. He fell in with my suggestion that he should test the pharmacological action of extracts of the fæces of lower animals, apparently healthy men, and of patients in the wards. By arrangement, the source of the individual extracts in the earlier series of experiments was not known to him prior to the determination of the result. The extracts were prepared as follows. In the lower animals six ounces approximately of fæcal matter were collected, care being taken to prevent admixture with urine. The specimens examined were for the most part obtained from animals which were under my own observation, the dietary being known; in the pig and sheep the contents of the bowel were collected by me personally at the slaughter-house from newly killed animals. The fæces of a healthy judiciously fed horse, pig, and sheep are virtually odourless; in the cow the fæces may be odourless, but frequently show evidence of slight putrefaction; the fæces of the cat emit a strong putrefactive odour. The fæces were extracted with plain tap water, repeated agitation being carried out, and subsequently filtered. The filtrate obtained varied in colour, some extracts being highly pigmented, others much less so. The extract was then filtered by passing through a porcelain filter to remove the bacteria present, and its sterility subsequently determined by bacteriological examination. This provided the filtrate referred to as the pigmented extract. In many instances the pigment matter in the extract was removed by charcoal, in order to determine whether any reaction obtained was due to the presence of bile pigment; such filtrate is referred to as non-pigmented extract. The fæces of the human subject were treated similarly, observations being made on the filtrate obtained from the use of a first enema of 2–2½ pints of plain water—control observations were made with distilled water and normal saline—and from a second injection of a similar nature administered after the first had been returned. Some additional observations were made on the action of an extract prepared from fluids obtained after 12–13 pints in all had been administered, but these are at the moment of subsidiary interest.

Experiments were directed to ascertain the following points: 1. The effects, if any, on the blood pressure of cats, of the original extracts of the fæces, as described above (pigmented extracts). 2. The effects if any, of the same extracts after removal of the pigment by charcoal (pigment-free extracts). 3. Any modification of the action induced by subjecting the extract to boiling for ten minutes.

EXPERIMENTS BY DR. DE.

A number of extracts prepared from the bowel wash-outs of men in health and disease and from the fæces of lower animals were tested to observe their effect on blood pressure of cats. The extracts tested were clear fluids, free from any suspended matter and varied in colour from very light straw to deep amber; the extracts from the first wash-out were generally darker in colour than those from the second. The reaction of the solutions was mostly on the alkaline side, the pH varying from 6·5 to 8·9. The extracts from which the pigmented matter had been removed by charcoal were perfectly clear solutions. The experiments were done on cats weighing generally from 2·5 to 3 kg. The animals were anæsthetised with paraldehyde and ether. The injections were given slowly, and so far as possible at a uniform rate, into the jugular vein, and the carotid blood pressure was recorded in the usual manner.

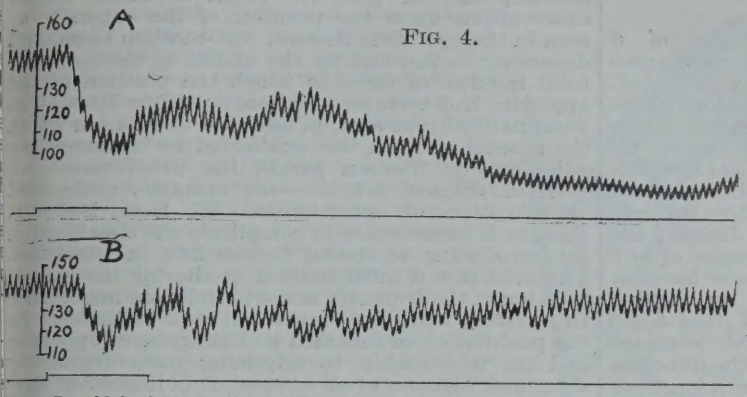
To obviate any error due to the amount of fluid injected, control observations were made with similar amounts of distilled water, tap water or saline. In the course of the experiment it was deemed advisable to test the effects of administration of the extract by injection into the femoral vein. The amount injected ranged from 1 c.cm. to 20 c.cm., and in a few cases to 30 c.cm.

Experiments with extracts from the fæces of animals.—Observations were made on the effects of extracts prepared from the fæces of sheep, pig, horse, cow, calf, and cat. The extracts from sheep (pH 7·6), pig (pH 8·1), and horse (pH 7·5–7·6) gave no fall in the blood pressure (Fig. 1). 20 c.cm. of an extract from cow (pH 7·5) and calf (pH 7·3) and 10 c.cm. of extract from cat (pH 7·1) reduced the

systolic blood pressure from 137 to 80, 130 to 52, and 112 to 63 mm. of mercury respectively (Fig. 2). The depressor effect of the extract from cat was to a marked extent destroyed by boiling the extract in water bath for 10 minutes.

Extracts from apparently healthy stools.—Extracts from three apparently healthy subjects were tested. The extracts

FIG. 4.



Cat. Paraldehyde and ether. Blood pressure. A shows the effect of injection of 10 c.cm. of the pigmented extract from the first wash-out of a case of melancholia. Note the marked fall in pressure, slowly recovered from. B shows the effect of injection of 10 c.cm. of the same extract after boiling in water bath for 10 minutes. Note the reduction in the depressor effect. Scale = blood pressure in mm. of mercury.

pH 6·5 to 7·6) caused a very slight or no fall of blood pressure when 20 c.cm. was injected (Fig. 3). Boiling did not materially alter the action.

Extracts from unhealthy bowel wash-outs.—Observations were made with extracts of the fæces from cases of melancholia, pernicious anæmia (pH 6·7), dysentery (pH 8·1), chorea (pH 8·4–8·9), disseminated sclerosis (pH 6·7), heart disease with impaired digestion (pH 6·5), high blood pressure (systolic blood pressure 175 in an individual of 65 years), (pH 6·9–7·0), bulbar paralysis, jaundice, diabetes mellitus (pH 6·5–6·6), subacute nephritis (pH 7·2–8·9), and pleurisy. These showed a fall of blood pressure. The results were in marked contrast to those obtained from the apparently normal subjects. A distinct lowering of the blood pressure was induced as illustrated in the figures. Fig. 4A illustrates the effect of injection of 10 c.cm. of the pigmented extract from the first wash-out of a case of melancholia. The blood pressure fell from 138 to 100 mm. of mercury, and the recovery was slow. Fig. 5 shows the effect of injection of 20 c.cm. of the pigmented extract from the first wash-out of a case of dysentery. The reduction of the blood pressure in this case was from 130 to 74 mm. of mercury. Fig. 6A shows the effect of injection of 10 c.cm. of extract from a case of heart disease with impaired digestion. A marked fall of blood pressure from 132 to 80 mm. of mercury was seen in this case also. Fig. 7 illustrates the fall of blood pressure with 1 c.cm. of extract from a case of pernicious anæmia. It shows the fall of blood pressure from 180 to 103 mm. of mercury with the extract from the second wash-out, while with the extract from the first wash-out the fall of blood pressure was from 163 to 130 mm. of mercury.

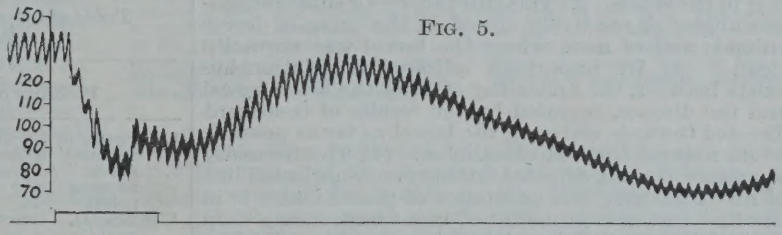
Effect of the filtrate from which pigment has been removed by charcoal.—In the cases of jaundice, dysentery, melancholia, and subacute nephritis, no fall in the blood pressure was obtained. Fig. 5 shows the effect in a case of dysentery with a dose of 20 c.cm. of the original extract.

Effect of the filtrate after boiling.—The extracts from cases of pleurisy, dysentery, diabetes mellitus, pernicious anæmia, and heart disease with impaired digestion, when boiled in a water bath for 10 minutes, showed no change in the depressor effect when compared with the original solution. Figs. 6A and B show the effect of injection of 10 c.cm. of the extract, before and after boiling, from a case of heart disease. In the subjects with chorea, melancholia, disseminated sclerosis, and high blood pressure it appears that a part of the depressor action was destroyed by such boiling. Figs. 4A and B show the comparative effect in a case of melancholia when 10 c.cm. was injected. In a case of subacute nephritis the depressor action was completely destroyed by boiling.

Extract from first and second wash-out.—The extract from the first wash-out generally gave a greater fall of blood pressure than that from the second. Exceptions to this were, however, noticed in the case of pernicious anæmia.

Effect of injection into femoral vein.—The results of injection of similar doses of the extract into the femoral vein showed practically the same effect as that of injection into the jugular vein.

FIG. 5.

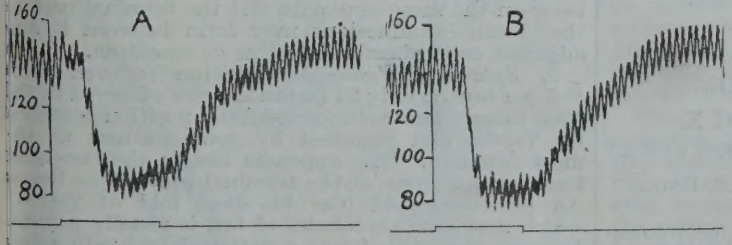


Cat. Paraldehyde and ether. Blood pressure. Shows the effect of injection of 20 c.cm. of the pigmented extract from the first wash-out of a case of dysentery. Note the marked fall in the blood pressure slowly recovered from. Scale = blood pressure in mm. of mercury.

Summary.

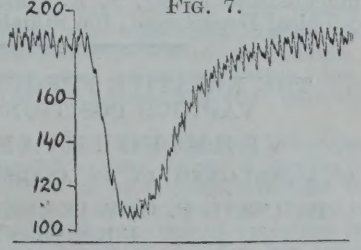
(1) The extracts from the fæces of sheep, horse, and pig gave no fall of blood pressure; those from cow, calf, and cat produced a marked fall in the blood pressure. (2) The extracts from the contents of the apparently healthy bowel gave very little or no fall of the blood pressure. (3) A fall of blood pressure was obtained with the extracts in the various diseases investigated. (4) The depressor effect obtained by injection into the jugular vein was

FIG. 6.



Cat. Paraldehyde and ether. Blood pressure. A shows the effect of injection of 10 c.cm. of extract from a case of heart disease with impaired digestion. Note the marked fall of blood pressure. Time = 2 seconds. B shows the effect of 10 c.cm. of the same extract after boiling in a water bath for 10 minutes. The depressor effect has not been altered by boiling. Scale = blood pressure in mm. of mercury.

FIG. 7.



Cat. Paraldehyde and ether. Blood pressure. Shows the effect of injection of 1 c.cm. pigmented extract from the second wash-out of a case of pernicious anæmia. Note the fall in the blood pressure. Scale = blood pressure in mm. of mercury.

equally obtained when the fluid was injected into the femoral vein. (5) The varying results recorded from the injection of the original extract and the extract, as obtained by treatment with charcoal and by boiling, appear to indicate that there is more than one toxic substance present.

Conclusions.

These experiments prove the existence of a hitherto unrecognised toxic substance or substances in the fæces in the different diseases investigated. The absence or—keeping in view the limitations in the amount of extract employed—relative absence of this substance as observed in lower animals, opens up questions of great physiological and clinical interest. These are enhanced by the results obtained from the examination of apparently healthy adult subjects living on a judiciously planned mixed dietary, the criteria of health being the complete absence of any symptoms or signs of disease, *with the lower bowel in the naturally clean condition intended by nature.* Without speculating on the nature of this toxic substance or substances, difficult and complex questions arise in regard to variations in the direction of abnormal manufacture of the toxic principles, their undue retention, and alteration in the absorptive power of the lining membrane of the bowel. The results of the experiments recall the researches of Dale and Barger, Mellanby, Lewis, and others, on histamine and histamine-like bodies present in the lining membrane of the bowel; their possible relationship to various researches on abnormal proteose substances also require investigation.

(1) For the first time a powerful toxic substance has been shown in the fæces of the diseases studied, in which the unaided senses revealed excessive putrefaction in the stools. (2) This substance—or substances—was absent or relatively absent in the fæces of lower animals and of men, where the bowel was normally clean. (3) An important ætiological relationship exists between the unhealthy state of the lower bowel and the disease, revealed by the results of treatment directed towards restoring the bowel as far as possible to its natural state of cleanliness. (4) The necessity of attention being directed to this much-neglected line of investigation; the assistance of practitioners is in the first instance probably of more importance than that of the specialist or laboratory worker. (5) The study of disease on the lines suggested accentuates the need for a closer study of the influence of heredity and of variations in the individual reaction to disease; it also involves the closer application of Listerian principles to medicine as opposed to surgery.

I have much pleasure expressing my cordial appreciation of the admirable facilities afforded by Prof. Clark for the work carried out in his department and for various helpful suggestions; also my indebtedness to Mr. T. E. Condon, of the Pharmacological Department, for valuable assistance.

THE RELATIVE FREQUENCY OF THE VARIOUS POSITIONS OF THE VERMIFORM APPENDIX

AS ASCERTAINED BY AN ANALYSIS OF 5000 CASES.*

BY CECIL P. G. WAKELEY, F.R.C.S. ENG., F.R.S. EDIN.,

LECTURER IN ADVANCED ANATOMY, UNIVERSITY OF LONDON, KING'S COLLEGE; ASSISTANT SURGEON, KING'S COLLEGE HOSPITAL, AND BELGRAVE HOSPITAL FOR CHILDREN;

AND

REGINALD J. GLADSTONE, M.D. ABERD., F.R.C.S. ENG.,

READER IN EMBRYOLOGY AND LECTURER ON ANATOMY, UNIVERSITY OF LONDON, KING'S COLLEGE.

THE literature concerning the position of the cæcum and appendix is vast; but notwithstanding the excellent work which has already been done, there is a general feeling that the individual experience of many surgeons and anatomists does not conform with the statements that have been published and accepted with regard to the relative frequency of the different positions of these organs. It was on this account that in 1914 we began to make careful observations upon the position of the appendix as seen in the operating theatre, post-mortem room, and dissecting rooms, and by the middle of this year the total number of cases in which the position of the appendix had been recorded amounted to 5000. These cases naturally include, in addition to those in which the normal position was unaffected by inflammatory adhesions or traction bands, the usual cases met with in surgical practice—for example, acute and chronic cases of appendicitis. We have, however, thought it unnecessary to complicate the classification by introducing accidental factors into the statistics. The influence of inflammation in altering the normal position of the appendix is not of sufficient importance to interfere with the general value of statistics. As the position of an inflamed and gangrenous appendix and its relationship to adjoining parts frequently determine the site of an abscess, it is important that the surgeon should have some knowledge of the relative frequency of the various situations in which the appendix may be found, and its relationship to the surrounding pouches and folds of peritoneum.

A good deal of misconception arises from the use of certain terms for the folds of peritoneum and fossæ around the cæcum and appendix. As it is of the greatest importance that these names should denote a definite condition, we have thought it necessary to define clearly in the following table what we understand by the terms employed in this article.

Table showing Positions of the Appendix, with their Relative Frequency.

Positions of appendix.	No. of cases.	Per cent.
1. Anterior or pre-ileal	47	0·94
2. "Splenic" or post-ileal	25	0·5
3. "Pelvic," on psoas muscle, near or hanging over the brim of the pelvis	1606	32·11
4. Subcæcal, beneath the "caput cæci"	101	2·02
5. Post-cæcal and retrocolic	3219	64·38
6. Ectopic	2	0·04

The Various Sites of the Appendix and Associated Peritoneal Conditions.

1. The *anterior* or *pre-ileal* position is rare (0·94 per cent.). The tip of the appendix is directed upwards and forwards over the terminal part of the ileum. The meso-appendix is long and there is usually a small ileo-cæcal fold. Should the appendix become inflamed, abscess may occur either in the space included between the meso-appendix and the terminal part of the ileum, or adhesions may form between it and adjacent coils of small intestine or omentum.

2. *Splenic* or *post-ileal* position is even rarer (0·5 per cent.); only 25 instances were observed in the 5000 cases. This is the well-known position described by Treves and regarded by some authors as the most common. The appendix lies in the ileo-cæcal fossa, under cover of the terminal part of the ileum. An ileo-cæcal fold (the bloodless fold of Treves), which may contain lobules of fat, is usually present. In some cases this forms a flattened fold with a free rounded border resembling a large appendix epiploica; at other times it is a crescentic fold with a sharp free border, directed to the left and passing from the anterior aspect of the terminal part of the ileum and the adjacent part of the cæcum to the root of the appendix or its mesentery. If inflammation of the appendix should occur when it is in this position, mesenteric thrombosis, leading to portal pyæmia, is likely to ensue. This we regard as the most dangerous position the appendix may assume.

3. The *pelvic or descending* position occurs in 32·11 per cent. of our cases. The tip of the append-

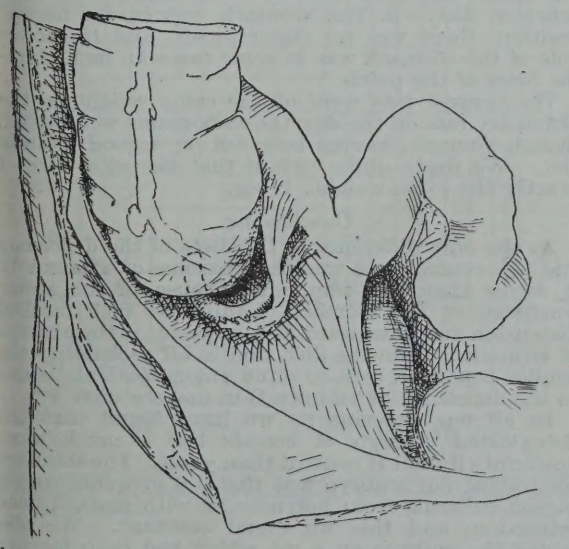
* Abstract of a paper read before the Anatomical Society of Great Britain and Ireland on Nov. 25th, 1927.

is usually directed downwards on the psoas and may hang over the brim of the pelvis; it is not infrequently associated with a genito-mesenteric fold which causes a downward kink of the terminal part of the ileum. This may lead to obstruction with resulting dilatation of the proximal portion of the gut, as originally pointed out by Arbuthnot Lane. It is probable that the position of the appendix in these cases is determined by the genito-mesenteric fold, which lies to its left side and passes vertically downwards from the posterior aspect of the ileum or left side of the mesentery to the internal abdominal ring, or, in the female, to the ovary. This relationship is important in connexion with the establishment of a secondary connexion between the lymphatic vessels of the ovary and appendix. Should inflammation ensue in an appendix overhanging the pelvic brim in a female, it may become adherent to the right ovary, and pain may occur in the right iliac fossa during menstruation. Such an appendix may also become adherent to either bladder or rectum and be the cause of painful micturition or defæcation; and should an abscess form it may discharge into the bladder or rectum.

4. The *subcœcal* position of the appendix (Fig. 1) beneath the caput cæci was present in 2·02 per cent. of cases. The appendix with its mesentery is twisted in a clockwise direction from left to right and its tip is usually directed upwards. If an ileo-cæcal fold is present it may cover the root of the appendix. In the specimen illustrated a genito-mesenteric fold was present, with a downward kink of the ileum. If inflammation should take place with the appendix in this position an abscess may form, and may discharge through the fascia iliaca into the substance of the iliacus muscle. Such a condition may give rise to spasm of the muscle and consequent flexion of the hip-joint.

5. The "*post-cœcal*" and *retrocolic* positions. This

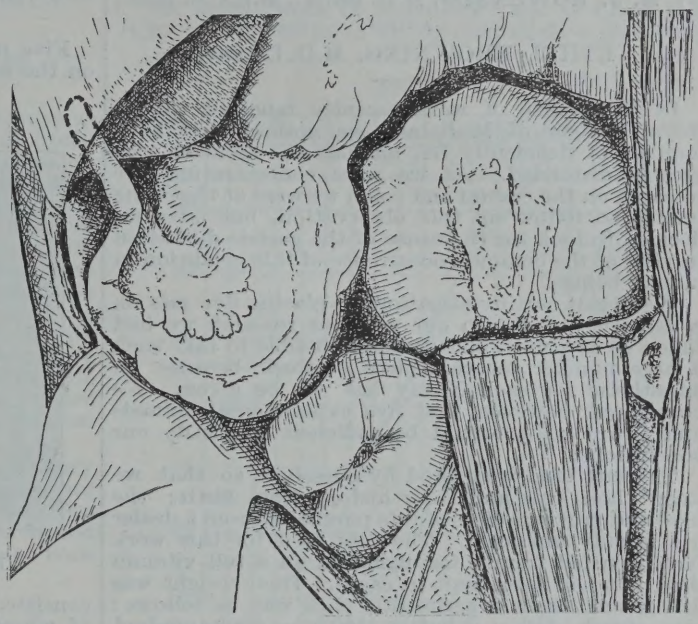
FIG. 1.—*Subcœcal Position.*



The appendix lies in the iliac fossa, with the apex directed upwards. There is a well-marked ileo-cæcal fold containing fat, which lies in front of the root of the appendix and its mesentery. There is also a genito-mesenteric fold, which has produced a downward "kink" of the terminal part of the ileum.

is the most common situation of the appendix. In our series there were 3219 cases representing 64·38 per cent. This is in accordance with the general experience of surgeons and anatomists at the present time, but differs markedly from the statistics which

FIG. 2.—*Ectopic Position: Prehepatic.*



The tip of the appendix is directed upward beneath the right half of the subcostal arch, and superficial to the right lobe of the liver. The cæcum is conical, and gradually tapers into the root of the appendix. It lies in the right lumbar region, and the ascending colon, which is superficial in position and very short, passes without any sharp hepatic flexure directly into the transverse colon. There is a well-marked ileo-cæcal fold containing lobulated fat.

have been published by previous writers and quoted in many of the standard text-books. This may be accounted for, partly by the difficulties which arise from one group overlapping another, and partly from the subdivision of the posterior positions, which are essentially the same, into two or more groups, thus masking the true frequency of the most common type. For instance, the tip of the appendix may be directed towards the spleen and thus be classed as splenic or post-ileal in position. It is, however, essentially retrocæcal in position. As stated in a previous communication,[1] the retrocæcal type of appendix may be found: (*a*) free in a post-cæcal or retrocolic pouch of peritoneum; (*b*) held in contact with the cæcum or ascending colon by a short mesentery; (*c*) adherent to the cæcum or colon, which, with the appendix, forms the anterior wall of a retrocolic pouch of peritoneum; (*d*) behind the cæcum and ascending colon, but, owing to obliteration of the retrocolic pouch, entirely extraperitoneal.

There is no doubt that inflammatory changes occurring in the appendix may cause a perfectly free appendix in position (*a*) to become adherent to the cæcum and so come into subdivision (*c*). There is also, however, a considerable amount of variation in the degree to which the cæcum and ascending colon become adherent to the posterior abdominal wall and iliac fossa in the course of normal development, apart from any secondary adhesion caused by inflammation.

6. The ectopic position of the appendix is excessively rare; only two cases have occurred in our series. In one the appendix was prehepatic in position (Fig. 2), while in the other it was lying free, with the cæcum below the stomach and transverse colon.

THE RELATION OF DEFICIENCY OF VITAMIN B TO ATONY OF THE STOMACH.

By M. J. ROWLANDS, M.D. Brux., M.R.C.S. Eng.,
AND
ETHEL BROWNING, M.D. Liverp.

In the course of work recently reported to the Royal Society of Medicine [1] we noticed that in a number of deficiently fed animals the stomach was greatly distended. As we were concentrating our research on the cæcum and colon we were at that time unable to follow up this observation, but later we decided to look for the cause of the gastric dilatation in view of the common occurrence of this condition in human beings.

We began our investigation by placing five rats on a deficiency diet. In our previous research we had taken 50 as a unit, but it was impossible to take such a large number for this piece of work because an anæsthetic for each X ray has to be given. We considered, however, that five experimental animals and five controls would be sufficient to justify our conclusions.

The rats used were bred by ourselves, so that we knew their ages and their history from birth; the ages and previous diets of rats purchased from a dealer are usually unknown. The rats used for this work had been fed from a fortnight old on a full vitamin diet, but had been kept in cages. Their weight was 120 g. and their experimental diet was as follows: rice starch, 650 g.; butter, 100 g.; devitaminised casein, 200 g.; salt mixture, 50 g. Owing to the difficulty of keeping rats on this diet for more than three or four weeks we decided to add 1 per cent. yeast extract, which enabled us to keep them alive for six weeks. At the end of this period the rats

Fig. 1. Fig. 2.

Radiogram of rats fed on a diet deficient in vitamin B, showing ptosis and dilatation of the stomach.

readily ate a meal of barium carbonate made into pilules with bread crumbs, milk, and sugar. We intended to take the radiograms one hour after the meal, but owing to a breakdown of our plant they had to be taken three and a half hours after the meal. Whilst realising that the work would have been much more satisfactory had we been able to radiograph the animals within an hour of the barium meal, we nevertheless feel that the results justify publication. In several of the radiograms a big air-space was noticed in the upper pole of the cardiac end. Figs. 1 and 2 are radiograms of deficiently fed rats.

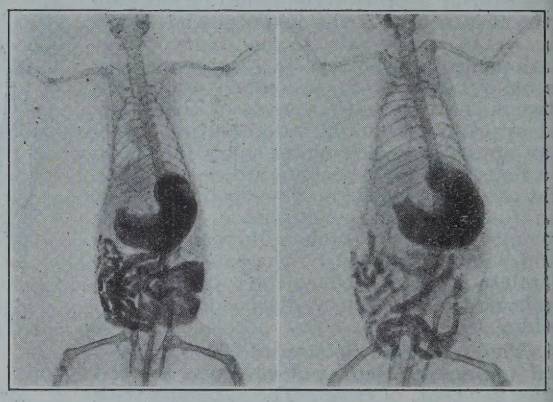
The following points we consider of importance: 1. The distension was almost entirely in the cardiac portion of the stomach, and not in the pyloric region. 2. The distension was in an upward direction. 3. Apart from the distension there was marked visceroptosis, and in some of the animals the lower pole of the stomach was at the brim of the pelvis. 4. In some of the rats the distension was so great as to be visible externally.

[1] Rheumatoid Arthritis: Is it a Deficiency Disease? Proc. Roy. Soc. Med., 1927, xx., 41.

Control Animals.

Five rats bred in the same way and originally fed on the same diet were taken as controls. Their diet

Fig. 3. Fig. 4.



Radiogram of control rats fed on normal diet.

consisted of sterilised meat meal, detoxicated embryo of wheat (bemax), barley meal and middlings, with 2 per cent. cod-liver oil and 2 per cent. bone-meal, thus ensuring a sufficient amount of vitamin B, which was lacking in the diet of the deficiency rats. These rats were given a barium meal, and a radiogram was taken three hours later. Figs. 3 and 4 are representative of the control radiograms. It will be seen that owing to the long interval a large amount of barium had left the stomach, but enough remained to give the outline of the stomach itself.

The following points are to be noted: 1. There was no enlargement of the cardiac end. 2. The size of the stomachs of the rats fed on a full vitamin B diet was about one-third of those of the animals fed on a deficient diet. 3. The stomach was in its normal position, there was no visceroptosis, and the lower pole of the stomach was in some cases an inch above the brim of the pelvis.

The control rats were of the same weight as the deficiency rats on the day the radiograms were taken, though younger, having been fed on a good vitamin diet. We made quite certain that the rats were of exactly the same weight, 110 g.

Conclusions.

As the only difference in the diets of the deficiency and the control rats was the presence of vitamin B it seems that the commonest cause of an atonic condition of the stomach, leading to such marked distension and downward displacement, is the absence of vitamin B from the diet, and in all probability the similar condition seen so often among patients is due to the deficiency of vitamin B in modern diet.

In all our experiments we have found that the detoxicated embryo of cereals has a much more powerful vitamin B content than yeast. The standard for testing our embryo was that 1·0 g. would cure a pigeon suffering from polyneuritis with marked head retraction, and this we found constant. We also tested the embryo on a rat which had been for five weeks on a diet deficient in vitamin B and had developed complete paralysis of the hind legs and convulsions. It was almost miraculous to see how rapidly this rat recovered; within an hour of taking the embryo the convulsions entirely ceased and the rat was able to move its hind legs.

The histological findings will be described by us in a later paper.

Clinical and Laboratory Notes.

A NOTE ON THE TREATMENT OF PRIMARY OR ESSENTIAL MARASMUS BY OSTELIN.

By Kenneth McFadyean, M.R.C.S. Eng.

The term "primary" or "essential" marasmus is applied to passive wasting commencing at birth, or within two weeks of birth, and for which no cause other than a vitamin deficiency has been discovered. The existence of this condition has long been recognised, and Still has suggested that it is due to an inherent error of metabolism. Without careful investigation of a much larger series of cases than the present one, the part of heredity in causation cannot be determined. Still's statement, that he has seen successive children in the same family develop the condition at the same age, should be borne in mind. Every case is remarkable for the striking absence of all symptoms other than passive wasting, which will persist for months without giving rise to further symptoms.

In this series of cases, common causes of secondary marasmus, including lowering of body temperature and rickets, were carefully eliminated. In two cases the absence of rickets in the bones was established by X ray examination. All eight patients have been

fed on a diet of scalded undiluted cow's milk. The writer's experience, in common with that of many other observers, is that milk thus raised to a temperature of 100° C. for a few minutes is sufficient in vitamin content for most children. Such a degree of heat has no influence on the vitamin A, B, or D content of the milk. Vitamin C is probably almost entirely destroyed, but is apparently of little importance. In essential marasmus the addition of vitamins A, B, or C to the diet fails to produce any benefit. The results of this series of cases suggest that the condition is invariably curable by the administration of vitamin D, but this is no proof that the absence of vitamin D is the sole cause of the condition.

The recent work of Steenbock [1] and of Chick and Roscoe [2] demonstrates the marked relative deficiency

of vitamin D in ordinary cow's milk and its complete absence from the milk of cows fed on oil-cake. This deficiency is not increased in the smallest degree by scalding, for vitamin D resists oxidation even when exposed to 100° C. for 12 hours. The fact that vitamin D deficiency appears to be largely responsible for marasmus in young infants and for rickets at a later period accords with some of the recent experiments of Chick and Roscoe.[3] These workers showed that a diet deficient in vitamin D might result in arrest of growth, but that typical rickets is far from being an invariable result.

In all cases vitamin D has been supplied in the form of ostelin, a proprietary preparation of the unsaponifiable fraction of cod-liver oil. An analytical record of the preparation has appeared in The Lancet (1927, ii., 508).

Two cases are specially interesting as both children were regularly exposed to the sun's rays, and though both pigmented well, neither made any progress until vitamin D was added to the diet. One of these children was living under excellent hygienic conditions in the hands of a trained nurse. The second was in a nursing home for nine weeks from birth under careful and constant supervision.

Case 1.—The infant was delivered after artificial induction of labour at the end of the thirty-sixth week of pregnancy.

[1] Jour. Biol. Chem., 1922, liii., 21.
[2] Biochem. Jour., 1926, xx., 632.
[3] Ibid., 1926, xx., 137.

The mother, aged 41 years, had severe toxic albuminuria of pregnancy, which terminated fatally.

Birth weight 4 lb. 12 oz. Fed on cow's milk diluted—4 oz. of milk and 8 oz. of water in 24 hours. End of second week: Passive wasting was the only symptom. Weight 4 lb. 10 oz. Citrated whole milk was then given. Third week: No fresh symptoms. Weight 4 lb. 12 oz. Characteristic facies of marasmus. Vitamin C (orange juice) added to each feed. Fifth week: No fresh symptoms. Child strikingly marasmic. Weight 4 lb. 13 oz. Vitamin B (butter and malted carbohydrates) added to each feed. No orange juice. Seventh week: No fresh symptoms. Weight 5 lb. Eighth week: Weight 5 lb. 1½ oz. Vitamin D (ostelin) added to each feed. No orange juice, butter or malted carbohydrates given. The weight then increased as follows. Ninth week: 5 lb. 6½ oz.; tenth week: 5 lb. 13½ oz.; seventeenth week: 8 lb. 8 oz.; thirty-second week: 14 lb.

From first to last no alteration was made in the basic food, method of feeding, or other environmental factor.

CASE 2.—The infant was delivered by normal labour at full term. The mother, aged 23 years, was healthy.

Birth weight 8 lb. Natural feeding. End of second week: No symptoms. Weight 8 lb. Fourth week: Weight 8 lb. 8 oz. Already marasmic in appearance. No other symptoms. Artificial feeding with scalded cow's milk instituted. Sixth week: Weight 8 lb. 6 oz. A little sickness. Milk diluted and vitamin C (orange juice) added. Eighth week: Weight 8 lb. 6 oz. Diet altered to Allenbury's food. Twelfth week: Weight 8 lb. 1 oz. Some sickness. Diet of diluted cow's milk restored. Sixteenth week: Weight 8 lb. 8 oz. Whole milk given. Twentieth week: Weight 8 lb. 8 oz. Vitamin D (ostelin) added to each feed. The weight then increased as follows. Twenty-first week: 9 lb.; twenty-fourth week: 11 lb.; twenty-eighth week: 13 lb.; thirty-second week: 15 lb. 2 oz.; thirty-sixth week: 16 lb. 8 oz.

Both infants were regularly exposed to the direct rays of the sun.

A NOTE ON
SQUINT CURED BY SIGHT EXERCISE.

By KENNETH R. SMITH, M.D. LOND.,
LATE R.A.F. MEDICAL SERVICE.

THE two following cases of squint came to my notice while acting as medical officer in charge of troops at a barracks military hospital.

H. S., a boy of 15 attached to the band of the —th Dragoons, presented himself at sick parade early in May, 1927, on a question of his glasses. He had marked convergent strabismus, but good sight in each eye separately. He stated that he had been supplied with glasses at the age of 5 for the treatment of the squint, and had undergone two operations for its cure at the Central London Ophthalmic Hospital in 1924 and 1925. This statement was confirmed by reference to the secretary of the hospital.

He was treated by exercise in the following way. A number of ordinary playing cards were placed in three sections on an exerciser stand[1] so constructed that three cards were exposed in a row. The centre card is seen by both eyes, the card on the left by the left eye only, and the card on the right by the right eye only. The group is seen much in the same way as we see out of doors, farther to the left with the left eye, and farther to the right with the right eye, but with both eyes at the same time in all the intervening part. The three cards on the stand form a group of separate tangible things, not simply pictures. No lenses or prisms are used and the two eyes can be seen and their movements observed. The exercising consists in stating the number of cards seen and naming the details of each, then removing a card and again naming details, and so on through the pack. At first the boy saw four cards, the centre one duplicated; after a few days' training he saw three cards occasionally, but the diplopia did not altogether disappear in the first three weeks' training. He then had a rest for a month and recommenced sight training at the end of June. He saw three cards without difficulty in binocular vision, and after a few days he was put to reading exercises, using his glasses.

[1] The exerciser is called the binoscope, and is obtainable from Messrs. John Bell and Croyden.

In the reading exercises the commencement of each line is seen by one eye, the central part of it by both eyes, and the termination by the other eye only. He had no difficulty with the reading exercises.

I last saw him on July 19th; all signs of the squint had disappeared, and he stated that he could see far better than before, and no longer got headaches or tired with reading his music. Inquiry has elicited that his condition was equally satisfactory on Sept. 29th.

While H. S. was carrying out his training exercises, C. F., a boy of 14, with conspicuous convergent squint, presented himself for medical examination as a recruit to join the army. He had normal vision in each eye separately. He was asked whether he played games; his reply was "Yes." Cricket?—"Yes." Which do you do better, batting or bowling?—"Batting, the ball will go to one side bowling." This boy was tried with the exerciser, and the three cards were carefully covered until he was ready to see them, and he was asked, as they were uncovered, "How many cards do you see?" His reply was, "Four—no, three." The diplopia was there, but was immediately replaced by binocular vision. Games had apparently kept this boy's eyes alert and active, so that as soon as he saw with both at the same time central vision with both followed immediately. But playing games had failed to bring about in the course of years what the exerciser enabled him to do at once—that is, *to see with both eyes at the same time.*

His cricket record appears to indicate that one-eyed sight is less efficient when we are ourselves in motion than when we are looking at a moving object.

AN UNUSUAL CASE OF
INVERSION OF THE UTERUS.

By C. L. LANDER, *D.S.O.*, *M.C.*, M.B. LOND.,
SURGEON, ROYAL ALBERT HOSPITAL.

THE following case seems to be worth reporting.

A primigravida, aged 23, was delivered of a female child on Feb. 27th by Dr. I. E. Harries, of Stoke. The labour was prolonged, and forceps were used. A "battledore" placenta was delivered an hour after the child. There was some post-partum hæmorrhage, and a moderate perineal tear, which was sutured. The puerperium was uneventful and the patient made excellent progress, except that catheterisation was required. On the ninth day the patient was instructed by the midwife in charge to sit out of bed and attempt to micturate spontaneously. Whilst making expulsive efforts in a sitting posture, the uterus suddenly became inverted and presented at the vulva. Dr. Harries was called and the patient was sent to hospital. I saw her a few hours later, when there was no shock or hæmorrhage. A smooth rounded tumour could be felt in the vagina; it was pale in colour. The uterus could not be felt above the pubes. The woman was comparatively unconcerned and thought that there was nothing wrong, as the uterus, which at first protruded from the vulva, had been replaced in the vagina by Dr. Harries.

A general anæsthetic was given, and I attempted to reduce the inversion. Finding it impracticable to do this manually, I used a blunt rounded metal instrument as a repositor. After making steady pressure upwards for some minutes the fundus gave way, and the instrument perforated the uterine wall at the fundus near the left cornu. I then opened the abdomen and was able to effect reduction by inserting a finger through the perforation and exerting steady traction upwards, with the help of an assistant's hand in the vagina making upward pressure. Even so, the reduction was quite difficult and took some time to effect. When completed, the small rent in the uterine wall was sutured and the abdominal wound closed.

The subsequent progress of the case was quite uneventful. At the time of the operation there was nothing apparently abnormal in the size or consistence of the uterus examined from both aspects.

BARNSLEY HOSPITAL EXTENSION.—A new wing of the Beckett Hospital, Barnsley, will be opened on Feb. 8th by the Duke of Northumberland. Towards a £40,000 extension scheme a grant of £13,400 was made by the Miners' Welfare Fund with a suggestion that this money should be used to provide an addition to the hospital which should be directly identified with miners and their families

Medical Societies.

ROYAL INSTITUTE OF PUBLIC HEALTH.

Lord Justice ATKIN presided at a lecture given at this Institute on Jan. 18th by Mr. ROLAND BURROWS, Recorder of Chichester, entitled

THE MEDICAL PRACTITIONER IN RELATION TO THE ADMINISTRATION OF JUSTICE.

Mr. Burrows said that many medical men undoubtedly felt aggrieved at the way in which they were affected by the processes of law, but it must not be forgotten that the interests of justice were paramount, for it represented the lubrication of civilisation. The problem before the medical practitioner might be essentially different from that before the judge and jury, although the two problems were really one, viewed from entirely different aspects. The doctor was concerned primarily with treatment; the court only with liability. For both purposes it was necessary to ascertain the facts as accurately as possible. A medical man called in to a patient alleged to be suffering from some mental disorder would consider, consciously or unconsciously, first of all whether he was so suffering and then whether he needed treatment, and if so, what the form of that treatment should be. The court would be concerned with the question whether the man was or was not responsible for his actions. The point at which he should undergo treatment occurred at a different stage from that at which he ceased to be responsible. The general public was rather more disturbed about what they believed to be medical views on crime and insanity than the medical profession had realised. One reason was that many medical men held that no insane person should be held criminally responsible. Others again talked in such a way that it was impossible to discover from them whether or not there was such a thing as a sane man in the world. The public were a little alarmed at what would happen in the administration of criminal justice if such views prevailed; it would certainly fall to the ground. The lecturer thought that most medical men held sane views about insanity, but the extreme and startling always caught the public attention.

Functions of the Medical Man in Court.

When a medical man came into court his function was to assist the court to give a correct decision on the facts. In treating a patient it was for him to decide to the best of his ability; he was a seeker after truth and responsibility lay with him. In the court he was an assistant. Many had argued that it was absurd to leave the decision of medical matters to a lay court, but it was the immemorial practice of this country to give an accused person the right to have questions of fact determined by a jury. The medical problem was on precisely the same footing as scores of other problems that arose in all branches of knowledge. Moreover, in the great majority of cases the medical was not the only problem arising, and the decision of the court must be a decision upon the whole of the facts. Whatever be its justification, we were faced with the actual working of the judicial system, whereby the medical man was not entrusted with the duty of deciding any point of medical knowledge. That working was not likely to be altered by any movement or argument; the protection of the public, the judge and the jury, would probably be maintained, at all events so long as present conditions lasted.

In the Supreme Court the power of calling in an assessor was hardly ever exercised except in the Admiralty Division. In county courts the medical assessor appeared in workmen's compensation cases. The assessor was not a judge; he decided nothing, although he was, of course, under the judicial duty of being fair and impartial. The court could, in fact, disregard the opinion of the assessor altogether, and had done so. The assessor was most valuable when the judge was sitting alone or with colleagues, and was very difficult to work when the judge sat with a jury. The jury were the judges of fact, and the assessor's function became that of advising the advisor of the jury. It was doubtful whether he could be of any real assistance; the medical man best assisted the jury from the witness-box. The assessor suffered from the disadvantage of not having been called in to examine the patient at the time. The cause of justice could not possibly dispense with the medical men who came on the scene and observed and prescribed at the time of the event. One principle governed all witnesses, that of telling the truth. The fact that, in practice, a witness was always called by one side or the other did not cast upon him in any way the obligation of being a partisan. All witnesses were called in to assist the court in arriving at the truth. The witness of fact was a man who had observed some fact in issue or relevant to the issue, and his duty was confined to informing the court of the facts which he had so observed. There were strict limits within which he was entitled to inform the court of his inferences and opinions. In actual practice it was impossible to confine a witness strictly to observed facts; even the plainest statement was compounded of what a man had observed and what he had inferred from his observations. An expert, on the other hand, was called because he had special skill and knowledge and could give his opinion on the facts. The significance of an observed fact might only be apparent to men with special knowledge and training.

Evidence of the General Practitioner.

The medical man often occupied a position midway between the witness of fact and the expert. He was frequently sent for at a material time, but the interpretation of the facts which he thus observed called for his special knowledge and training, and he was permitted to give the court the benefit of his opinions. The term "expert" was unfortunate, for it was used in two senses. A medical witness as a witness was necessarily expert, but within the profession there was another and smaller class of experts. The lecturer had often sympathised with the general practitioner called on to give evidence as an expert and expected to be an expert in a particular branch of knowledge where he claimed no such position. Lawyers were apt to pay insufficient attention to the circumstances under which a medical man was called in—cases of emergency where something had to be done at once, where there was no time for detailed examination or precise diagnosis. He might never see the patient again until called to court, and in the more leisurely atmosphere of the law he might be expected to be precise and detailed. Here came in the essential distinction between the problem of the doctor and the problem of the court; for purposes of treatment—the doctor's primary concern—the examination might be comparatively cursory, whereas to give proper evidence, to assist the court, it ought to be more lengthy. A good deal of resentment was caused by the practice of cross-examination, but the other party must, in fairness, have an opportunity of checking the accuracy of the evidence, and there was nothing to differentiate the medical witness from any other expert. It would not advance the cause of justice for him to give his evidence in the form of a report, and to give evidence orally without cross-examination would involve a complete change in the existing procedure. If the doctor were called as a witness by the court, as had been suggested, he would be cross-examined by both parties instead of by one. Moreover, cross-examination was an advantage to a competent and properly prepared witness, enabling him to clarify and expand his evidence and remove misconceptions. The honest witness would come out of the ordeal better than when he went in.

Conflict of Loyalties.

When a medical man was asked to reveal matters confidential between himself and his patient the rule

had been laid down that no medical man could refuse to answer a question. The "privilege" of the lawyer was really a privilege of his client, and essential to the administration of justice. The interest of justice was paramount. If the witness was called by his patient, the patient had to risk disclosures which he did not desire. Civil actions often put the general practitioner in a most difficult position. Anything which tended to prevent people being frank with their doctors was not to the public advantage. Cases must, however, be decided on a general rule, and the general rule always spelt hardship in particular cases. The matter had been extensively discussed; the lecturer's view was that there was no sufficient cause for amending the present rule, relaxation of which might lead to fraud and injustice.

Advice to the Medical Witness.

The doctor unused to giving evidence should remember first of all that his primary duty was to be accurate. He was called upon to assist very materially in the cause of justice, his assistance was regulated by the rules of procedure, applied by persons skilled in the working of them; he could therefore leave the conduct of the case to them. He should make himself acquainted, at least in outline, with the way in which his evidence could assist the court—i.e., with the issue to be tried. Then he should distinguish carefully between evidence of observed fact and inference. Fact easily flowed into inference, inference into opinion, and opinion into mere hypothesis. The experienced witness confined himself, in the first instance, to facts and to inferences which could with certainty be based upon those facts, leaving less certain inferences and opinions to be elicited by the lawyers if they wanted them, or were rash enough to ask for them. A witness was in a strong position when he said "I have observed certain facts; it follows from those facts that such a state of affairs exists," and was prepared to justify his statement both positively and negatively. If he could not draw one positive inference he should say what were the possible ones and then go on to state which, in his opinion, was the right one. If pressed further he should state his opinion definitely, openly, as a matter on which he would profess to give an opinion. He must expect to be challenged by reference to text-books, and should avoid relying more upon what he had read in works of authority than on his own observation and skill.

In conclusion Mr. Burrows urged the formation of a central medico-legal institute where experts could be trained and matters of mutual interest discussed by both professions.

Dogmatism a Disadvantage.

Lord Justice ATKIN said that no class of evidence was viewed more sympathetically by the bench than that of the doctor. An extraordinary number of cases, and an increasing number, seemed to depend upon the true appreciation of medical facts. There was no doubt that the ordinary practitioner was exposed to great difficulty when called upon to give evidence, and he (the speaker) had often sympathised with the medical witness. Although it might seem a paradox, the advocate who had especially prepared his case might be much better equipped than the expert to deal with the matter. The golden rule for the medical witness was to admit uncertainty if he felt it. Nothing could put a doctor in a firmer or more convincing position with the court than his refusal to be absolutely certain about everything. Indeed, if a man wanted to convince a jury it would be worth while saying "I am not quite sure," or "It may be so, but I don't know," once or twice whether he meant it or not! Generally speaking, bench and advocates trusted a doctor as he deserved, and he might face his duty in court with equanimity if he observed that simple rule. As the law stood at present a doctor was not privileged to maintain his patient's confidence. The claims of justice on one side had to be weighed against the claims of public health on the other. His lordship himself was of the opinion that in some cases, notably those connected with venereal disease, the claims of public health far outweighed those of justice. He would be very glad to see some change in the law, even that very limited alteration proposed in Dr. Graham Little's Bill. The courts allowed certain facts to be withheld—for instance, those disclosed to a legal advisor were withheld in the interests of justice, and those which concerned the State were withheld without any reference to the administration of justice. He failed to see why it might not be just as much to the interest of the State to withhold some facts dealing with the health of the individual as to withhold facts relating to armaments. He recognised the extreme public importance of mutual understanding between lawyers and doctors, and familiarity with each other's problems. He would like to see a general system of education in medico-legal matters to which both practitioners and advocates should have recourse. Every person concerned with the administration of justice should be instructed in the principles of medical jurisprudence.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

AT a meeting of this Society held on Jan. 18th, at which Dr. JAMES WHEATLEY, the President, occupied the chair, Prof. R. H. A. PLIMMER opened a discussion on

RECENT ADVANCES IN THE KNOWLEDGE OF FOOD.

He described a series of experiments on the vitamin B requirements of birds and animals, with his deductions therefrom. Lists of beri-beri-preventing foods had, he said, been prepared by several workers, but they had not established the quantities of these foods that were required in relation to the B-deficient part of the diet. The experiments he and his colleagues had performed had shown that a pigeon on a staple diet of 30 g. of white rice needed, for the prevention of polyneuritis, the addition of either 3 g. of lentils or egg-yolk, 4 g. of barley, 5 g. of brain, 20 g. of muscle, or 35 g. of milk. The latter two quantities approached the bird's total requirement of foods. The amounts of wheat germ (bemax) or yeast extract (marmite) required were about equal, viz., 3–5 per cent. of the total dried weight of the diet. The figure for dried egg-yolk was 18 per cent. The B-vitamin content of the diet was not absolute, but must be increased with the increase of diet of growing birds; this finding harmonised with the observation often made in the East that beri-beri appeared more readily in persons with a large appetite. Further experiments had shown that a definite relationship existed between the quantity of vitamin B required and the quantity of protein, of fat, or of carbohydrate consumed. The standard diet used consisted of fish meal, white rice, and cod-liver oil, and was thus free of B but sufficient in A and D. Birds did not require C.

On 90 parts of rice, 5 of fish-meal, 1 of cod-liver oil, and 9 of yeast extract, birds could be raised from a day old to maturity. When the fish-meal was raised to 30 parts, six birds out of eight died. Twenty parts, however, were tolerated if the yeast were raised to 16 parts. For the experiments on fat, cotton-seed oil was used to obviate any excess of A and D from cod-liver oil. It was found that the diet had to contain 16 per cent. of dried yeast to keep the birds in health. When the quantity was reduced to 12 per cent. the birds fared very badly. From this Prof. Plimmer inferred that children taking cod-liver oil ought to be given a substance rich in B-vitamin at the same time. The experiments on excess of carbohydrate in the diet had given similar results, and the series had demonstrated that each component of the diet had to be balanced by an adequate quantity of vitamin B. Post mortem the birds that had died from B deficiency, even if they had not shown symptoms of polyneuritis, had revealed signs of intestinal stasis with pale hearts and enlarged livers.

Subsistence Rate of Vitamin B.

The constant ratio shown by the experiments to be necessary between the total amount of food consumed and the amount of food containing vitamin B was, for chickens, one part of dried yeast to 8 or 12 parts of food. Pigeons did well on a ratio varying from 1 in 10 to 1 in 24. Rats could subsist adequately on 1 part in 48. No experimental data were available for man, but calculations based on the beri-beri-producing diets of the Japanese troops during the siege of Port Arthur, and on those of our own men at Gallipoli, suggested a ratio of between 1 : 10 and 1 : 24. For safety the higher figure should be taken. It was not so easy as most people believed to eat a sufficient quantity of vitamin B, as was shown by the work done on standardising foods in terms of their B value. Assuming a staple diet containing no vitamin B at all, the amounts of B-containing foods necessary were: marmite, 10 per cent.; peanuts, 20 per cent.; pulses, 27 per cent.; white barley, almonds, and chestnuts, 40 per cent.; egg-yolk, 50 per cent.; and potato, 80 per cent. Carrots and onions contained a little vitamin B, but green cabbage none. Cocoanut, unlike other nuts, was useless.

Vitamin B and Cell Nuclei.

Prof. Plimmer commented on the fact that young animals needed more vitamin B than did adults, and suggested in explanation that one of the chief functions of this vitamin was to build and repair cell nuclei. All the substances isolated as vitamin B belonged to the group of nucleic acids.

In the absence of Prof. J. C. DRUMMOND, Dr. M. J. ROWLANDS showed a number of slides illustrating the remarkable atrophy and disappearance of areolar tissue and of muscle from the intestinal walls of animals fed on B-deficient diets (see p. 180). He also mentioned work on rheumatoid arthritis read before the Royal Society of Medicine.

Dr. MARGARET EMSLIE pointed out that white flour was much easier and cheaper to use for cooking and baking, and would therefore probably continue in use among poor families. She had been greatly impressed by the value of bemax, at infant welfare centres, for anæmia, languor, constipation, and cardiovascular depression.

The PRESIDENT complained that persons in high positions, both in the Ministry and in the medical profession, had made assertions about food which were entirely unjustifiable. When interference with food, such as fractioning or sterilisation, was in question, the burden of proof ought to lie on the person "committing the offence." McCarrison's work had shown that natural foods generally contained the constituents necessary for life, but that danger arose with the first attempt at fractioning. Many persons said—apparently without any evidence—that it did not matter whether one ate wholemeal or white bread under present conditions, because of the variety of the modern diet. A labourer on 40*s*. a week ate hardly anything but bread, margarine, and a little sugar; for him eggs and other vitamin-B containing foods were out of the question. Moreover, very few of these foods, according to Prof. Plimmer, would do more than balance themselves.

In answer to questions, Dr. ROWLANDS stated that detoxicated embryo of wheat would cure even advanced case of degeneration of the stomach wall, and had been very beneficial in cases of rheumatoid arthritis.—Prof. PLIMMER considered that it was not necessary to balance every meal, so long as the whole day's food was properly balanced. Beer, he said, was so thoroughly filtered nowadays that it contained no vitamin B. The trouble in balancing the carbohydrate part of the diet arose from the sugar, which was highly concentrated, much more than from the white flour. He had never noticed any harm resulting from even an unlimited use of vitamin B.

MEDICAL SOCIETY OF LONDON.

TREATMENT OF PERNICIOUS ANÆMIA.

AT a meeting of this Society held on Jan. 23rd, Mr. HERBERT W. CARSON, the President, in the chair, Prof. F. R. FRASER opened a discussion on the treatment of pernicious anæmia, which, he said, practically meant the Minot-Murphy treatment. Feeding with liver had so altered the outlook of treatment and the prognosis of the disease that it was necessary to readjust one's attitude in regard to it. Last summer Minot and Murphy reported a larger series of cases than those with which they launched their first contribution—i.e., 105 cases—and confirmed the good results of their first set. They were also now able to announce the preparation from liver of a non-protein, non-iron-containing extract, which appeared to have the same action as had whole liver. That shifted ideas from a matter of mere diet to one of specific action. After the treatment not only was there a marked remission of the symptoms in a few days, but also a great change in the blood picture. Minot and Murphy were largely led to try liver for pernicious anæmia because it had many similarities to such diseases as sprue, pellagra, and beri-beri, and liver was beneficial in those, especially in sprue. At St. Bartholomew's Hospital, said Prof. Fraser, 19 cases of pernicious anæmia had been given the liver treatment. Six of those patients, however, were in the remission stage when the treatment was started, and in four others the observations were not complete or other methods of treatment were also used.

After taking half a pound of whole cooked liver, there occurred a marked temporary rise in the reticulocytes. This rise reached its maximum and then fell rapidly, and there followed a steady rise in the red cells and the hæmoglobin until they approached the normal. Coincidently there was a striking improvement in the general condition of the patient, especially, perhaps, in the mental condition. In two cases in which no other diagnosis than pernicious anæmia could be arrived at the treatment failed. One of those patients died, and the post-mortem examination provided no alternative diagnosis. The ten patients who were either in the remission stage when they came under observation or had had other forms of treatment than liver, had now been under observation for three to six months, and the results in them had been good; four had now a red cell count of over 5 million, two of over 4 million, one over 3½ million. One patient could not take the liver satisfactorily, but at the end of five weeks she had over 3 million reds and hæmoglobin 96 per cent.; she could not be observed longer. In one case the treatment had to be stopped because of heart trouble. One patient came under observation while having arsenical treatment, and it was not for some time that liver treatment was commenced. He did very well as judged by the symptoms, but at the end of four months he got acute appendicitis, perforation occurred, followed by peritonitis, and he died. At the time of his second admission with appendicitis four months after liver treatment was begun, the red cells were 5,100,000, the hæmoglobin 95 per cent., and the white cells 13,400.

There was a striking uniformity of immediate results of liver treatment in all the published series of pernicious anæmia, and equally remarkable was the fact that no such action ensued in the case of secondary anæmia. Here, therefore, was a therapeutic principle of which the profession had had no previous knowledge or suggestion. Sufficient time had not yet elapsed to enable judgment to be formed as to the capacity of liver to maintain these patients in the high condition of health to which it had restored them, or to prevent relapses. Minot told him that of 150 cases which had been followed for longer than three years none who had taken the liver treatment in the amounts recommended had relapsed.

Some showed on occasions a small decrease in red cells, but pushing liver at that time resulted in a restoration of the former figure. Studies by Peabody on the bone-marrow in pernicious anæmia showed that in the relapse stage of the condition the marrow was crowded with megaloblasts, which failed to come to maturity. Examination of bone-marrow in the remission stage produced by liver treatment showed the megaloblasts passing on to the megalocyte stage. Hence Peabody suggested that liver acted by imparting a stimulus to the developing red cells, and so enabling them to mature.

It was still uncertain what effect liver had on the nervous system. Though in the cases at St. Bartholomew's Hospital progressive changes had appeared during the liver treatment, it was possible that the approach of the blood to the normal and its maintenance in that state for some time would stay nerve changes. There was no evidence that the achlorhydria disappeared as a result of liver treatment; certainly it was present long before the anæmia became an entity. This fact rendered necessary the general treatment of the patient as heretofore, as a supplement to this new therapy, and especially the administration of hydrochloric acid and the giving of a generous and full diet. Before long, a reliable marketable extract should be on the English market; firms were already making it, and had consented to hold up its issue until the Medical Research Council was able to certify that the product was effective. When simple full liver was given prolonged boiling should be avoided.

Discussion.

Sir WILLIAM WILLCOX agreed that the liver treatment of pernicious anæmia was a great discovery. He commented on the similarities between sprue and pernicious anæmia, the former showing a definite streptococcal toxæmia and sore tongue. He had personally treated several cases of pernicious anæmia on these lines. These patients evinced a striking tolerance to liver, and it was remarkable how quickly the jaundice cleared up, the icterus index falling to normal. The liver treatment seemed also to act as an intestinal corrective, as there did not seem any necessity to resort to colon lavage or aperients, and the offensiveness of the stools was quickly lost. Under liver treatment, not only did leucopenia disappear, but the total leucocytes became normal. As yet no adequate explanation was forthcoming as to why liver acted in this way. He urged that the profession should not cease carrying out the other measures which had been found effective before this discovery was made; certainly the search for septic foci should be continued all over the body. Even now, transfusion might lift a patient over the stile and enable him to react better to the liver treatment. The giving of hydrochloric acid should not be abandoned. He was aware that for many years arsenic had been a kind of sheet-anchor in the treatment of pernicious anæmia, but nervous symptoms were then very apt to occur, and often he had been puzzled to know whether a patient's neuritis was due to the disease or to its treatment by arsenic. It was probable that arsenic and arsenobenzol treatment of pernicious anæmia would now cease.

Dr. HERBERT FRENCH said he was able to confirm what had been said from his own limited experience. In one case during seven weeks the hæmoglobin rose from 35 to 95 per cent., with no other treatment than that of liver by the mouth. This patient preferred it uncooked, and he was able to take it in a sandwich with a little watercress. Other and older treatments, he agreed, should not be forgotten; he remained in favour of transfusion, and thought it should be employed at an early stage, when the return to normal would be found steady and progressive. He preferred to give three transfusions of a pint each at intervals of about three weeks. That should now be supplemented by giving liver. While he had sometimes given arsenical treatment he had not found "606" of much use, and there was little necessity for trying it now.

The PRESIDENT said stress had been laid on the need for attacking cases of pernicious anæmia early, but nothing had been said about the early symptoms, an account of which would be welcome. Thirty-five years ago Dr. Samuel Gee had said one should never make a diagnosis of pernicious anæmia until malignant disease of the stomach had been definitely excluded—a very wise statement in days when biochemistry and X rays were not available as working aids.

Dr. WALTER BROADBENT spoke of two cases of pernicious anæmia under his care which did extraordinarily well with liver treatment plus a good deal of hydrochloric acid to drink.

Dr. R. A. YOUNG spoke of a profound case of the disease which was under his care. The man, aged 44, preferred to take the liver raw, with orange-juice. His return to a normal blood count was more rapid than was the disappearance of the symptoms. There was a striking rise in the eosinophile count. Possibly when liver was taken raw there was a risk of some parasitic infection. He had had a case of pernicious anæmia in which 0·2 g. doses of novarsenobillon produced a dramatic improvement; but as usual the achlorhydria persisted.

Dr. G. W. GOODHART spoke of work done at University College by Miss J. M. Vaughan and himself. He advised against making extract of liver substance on a small scale; it was too expensive in time, labour, and money. Ten cases had been treated under him with the extracts, but in only three had the red count gone up to over 4 million; there was a much quicker response in the hæmoglobin; most of the patients had retained their high colour-index. It was usual to assume that if an extract did not produce good results in 10 to 14 days, it was not good, but he thought a greater latitude should be given, as in one case, which had whole fresh liver treatment for two months without showing response, immense benefit occurred after three months.

Dr. P. B. SPURGIN gave a recipe for liver soup, and directions for preparing and cooking it.

Dr. PARKES WEBER asked whether observations had been made on cases of acute aplastic anæmia fed with liver. The two conditions seemed to him to be of similar nature.

Mr. ZACHARY COPE spoke of a case of secondary anæmia following massive intrathoracic suppuration which did not benefit by blood transfusions, but showed a rapid improvement when fed on fresh liver. He asked whether bone-marrow had a similar effect in pernicious anæmia.

Dr. C. E. LAKIN referred to a case of carcinoma of the stomach which despite the malignant disease showed an increase of red corpuscles after liver feeding.

Dr. BROWNING ALEXANDER thought liver-efficiency tests should be perfected. He felt sure pernicious anæmia was an infection, and the old treatment for it should not be lost sight of.

Sir LEONARD ROGERS drew a parallel between sprue and pernicious anæmia, and related cases in which liver soup produced a dramatic improvement in sprue. In the latter, too, a single transfusion of blood might bring about a cure.

Dr. LANGDON BROWN said that persistence of the achlorhydria in pernicious anæmia, despite the liver treatment, was the experience of most. In one patient of his who was given the treatment the leucopenia still persisted, therefore he could not consider her cured, though her red cell count was 4½ million. Liver treatment had not been successful in human beings suffering from secondary anæmias. He was not inclined to cease giving hydrochloric acid.

Prof. FRASER briefly replied.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ELECTROTHERAPEUTICS.

AT a meeting of this Section, held on Jan. 20th, with Sir HENRY GAUVAIN, the President, in the chair, the subject of

DIATHERMY IN RELATION TO CIRCULATORY DISTURBANCES

was opened by Prof. SIDNEY RUSS with a paper on the physics of diathermy. A few years ago, he said, he carried out some observations on a volunteer, a normal man with a normal temperature to commence with. He was able to pass a current of high frequency through that man, without raising the temperature as much as one degree. The body had a remarkable capacity for dealing with heat introduced into it so that no rise of temperature followed. Diathermy might prove to be an effective method of heating the body in cases of operation, when he believed the temperature of the operating theatre was conditioned by the need to keep up the temperature of the patient. Recently d'Arsonval had brought forward observations on the way in which heat was generated in different liquids by the passage through them of high-frequency currents. He used for this purpose saline, drinking-water, serum, and urine, and having sent a current through them the solution was diluted and the frequency of the oscillations increased, so that the same current resulted. All four fluids gave very similar physical characteristics. The heat developed in these solutions rose more or less on purely physical lines, but by diluting the liquid progressively it tended to lose its electrolytic properties and to become more dielectric. It was important, in the clinical use of diathermy currents, that medical men should have at their disposal a very accurate check on the voltage being employed by them. It was not difficult to so operate these circuits that a large current was sent with a comparatively small voltage, or a smaller current at a high voltage. The heating under those two conditions would be very different. Much of the knowledge as to the behaviour of large high-frequency currents in the body was due to Dr. Cumberbatch. It could not be assumed, however, that a strict parallelism held for strong as compared with weak currents. A chance observation by the speaker led him to believe that nerve-tissue was a very good conductor for weak high-frequency currents; that, however, needed corroboration. On one occasion a weak high-frequency current—i.e., less than 0·2 of an ampére—passed from hand to hand of one of his colleagues for not half a minute. Pins and needles sensations followed, and next morning a large part of the surface of the arm was devoid of sensation. Examination of cutaneous sensation showed an area of anæsthesia on the inner and ventral aspect of the right forearm, and this was bordered by a band of paræsthesia, the whole affected area corresponding with the cutaneous distribution of the ventral fibres of the internal cutaneous nerve. A cervical rib was the cause of the phenomenon.

The Clinical Aspect.

Dr. T. F. COTTON spoke of his experience of the application of diathermy in cases of disturbance of the cardiovascular system. Its value in the latter seemed to depend upon the production of heat in the body; he thought electrotherapeutists generally were agreed that this heat generation and its effect on the deep tissues of the body was the only special effect of diathermy. Lewis and his co-workers had provided a series of accurately recorded observations on the response of the blood-vessels of the skin to heat stimulation, and these studies should help to explain the mechanism of the response of the deep blood-vessels to thermal stimuli. Lewis considered that the reaction by active dilatation of the arterioles, venules, and capillaries to changes of temperature was a dual one. Heat lowered the tone of the walls of the small vessels, and the predominating influence of heat was to increase the concentration of vasodilator substances in the tissue spaces. This reactive hyperæmia with the increased blood flow was a mechanism of fine adjustment which governed the nutrition of the tissues. The metabolites released in the tissues had a histamine-like action, and were normal constituents of the tissues. When constrictor influences predominated, causing an alteration in the peripheral circulation, the release of the vasodilator substances caused the small vessels to dilate, the normal circulation was restored, and there was a better blood-supply to the tissues. There was also a reflex of central origin, which played a rôle in dilating small vessels and so improving the circulation. There occurred such a disturbance of circulation in the condition known as intermittent claudication, and hence diathermy should, theoretically, be a valuable remedial agent in this condition. He had seen the condition improved by diathermy and the pain lessened, but some subjects of it were refractory to the treatment.

Another condition in which constrictor influences predominated was acrocyanosis, but this diathermy only temporarily relieved; probably the constriction was of central origin.

With regard to high blood pressure and its treatment by diathermy, little was really known about blood pressure. But from the point of view of treatment, he thought patients with hypertension could be divided into two main groups: (1) those having symptoms which were directly due to the high blood pressure; (2) those whose symptoms were due to other causes. Patients belonging to the first group were definitely better when the blood pressure had been lowered some 20 mm. of mercury, and some of these had gross and obvious signs of structural disease of the cardiovascular system. Diathermy was of value in lowering the blood pressure. In the second group were patients whose predominant condition was renal disease, with renal insufficiency, and it was not rational to use diathermy for these; lowering of the blood pressure altered the permeability of the kidneys. In the same group were patients with symptoms of myocardial exhaustion due to auricular fibrillation. In these the blood pressure level could be affected by altering the pulse-rate by digitalis, but no good could be wrought by diathermy.

A further important group of patients were subjects of angina pectoris. In these, with high blood pressure, diathermy was a valuable therapeutic agent. Angina he looked upon as a symptom of myocardial exhaustion, frequently associated with coronary changes, but he did not think that the lowering of the blood pressure was the only factor in the improvement; possibly a more important factor was the reactive hyperæmia of the small vessels of the coronary circulation due to the application of heat, the quickening of the pulmonary rate of flow improving the nutrition. Another type of angina was that labelled "secondary angina," in which was no structural disease. Here it was probable there was a nutritional disturbance of the heart function, and the origin of it might be toxic. Patients whose pain prevented them carrying on their usual vocation, but who showed no sign of disease, were helpfully treated by diathermy, though other treatments were also good.

Dr. JUSTINA WILSON reminded members that arterial pressure could be raised either by increasing the power of the myocardium or by heightening the peripheral resistance. Of late years many workers thought that the basal condition was a functional disturbance in the walls of the smaller vessels, and that all the other phenomena were merely signs of enormous strain existing on the cardiovascular system. The primary cause was neither renal nor cardiac; in a large group the condition was due to toxins. The high blood pressure of lead poisoning, of eclamptic conditions, of prostatic enlargement, and of chronic interstitial and glomerular nephritis were well known. While she was working at the National Hospital for Diseases of the Heart it was found that in 40 per cent. of the cases there no toxic cause was

found for the increased blood pressure. The toxins in the other 60 per cent. were those arising from metabolic disease, syphilis, arterial sclerosis, climacteric, and other endocrine conditions.

The modern view on the pathogenesis of the condition under discussion was that it was a disturbance of the balance of the neurovascular mechanism, with some association of tonic and contractile function of the walls of the capillaries; 75 per cent. of the patients were found to have cholesterinæmia. In cases of chronic arterial hypertonia cerebral hæmorrhage frequently occurred. The cholesterinæmia thickened the membranes covering the vessel walls, so preventing their relaxation, and hence they were kept in a state of tonic arterial spasm. That, in turn, led to anæmia and changes in acidity, and to autolysis and necrosis.

There might be no symptoms of this condition for years, then certain effects on the nervous system might become evident, such as morning malaise, motor unrest; and this was later supplanted by great depression. Some patients manifested vertigo quite early, or at least giddiness, concentration and working-power diminished, and there was a condition of vasomotor angina. Renal involvement came later. At a fairly early stage the heart hypertrophied, then dilated, the apex-beat was heaving and displaced, the first sound was short, and the aortic second sound was ringing. Watching cases by means of X rays over a period of years one could see the development of atheromatous changes in the aorta which had not been there before. It could not be said, on her experience, that cerebral hæmorrhage was common in these cases, but 13 per cent. of a large series ended in true cerebral hæmorrhage—some by death, some by complete disablement.

Usually the symptoms came on about middle life. There were often quite long periods of spontaneous remission, which gave a fallacious idea as to results of treatment, as a natural remission of the kind might be attributed to the particular form of treatment being employed. In the third period of the condition the blood pressure was constantly anything from 180 to 210 mm., and later still this might mount up to even 240. Blood pressure curves should be taken four or five times a day, as extraordinary variations were noted at different times in the day.

There was no particular treatment for the first stage of the condition, while in the advanced stages the efforts had to be directed to giving relief. Much could be done to relieve symptoms and prolong life. When the blood pressure was very high, however, very little could be done by physiotherapy. Patients with this condition needed rest in the fresh air and away from their customary environment. Diet was important—i.e., practically vegetarian—fermentative substances and anything which further insulted the overburdened heart by loading the stomach being avoided. Oxygenated baths were found to somewhat lower the blood pressure. In cases of chronic constitutional high blood pressure ultra-violet light had proved, in her hands, disappointing. In many of the conditions she had referred to diathermy was helpful, and it was most useful in intermittent claudication, as it relieved pain so well, though it should be combined with a thorough treatment of the lymphatics. She was a believer in massage for the condition—i.e., a very light superficial stroking of the lymphatics of the skin, with vibratory treatment of the receptaculum chyli. As diathermy produced reactions in many sufferers from angina it was not advisable to give them daily applications of diathermy; sometimes pain and temperature followed the séance.

Dr. AGNES SAVILL spoke, from her own experience, of the benefit obtainable in a tired and exhausted person by the use of a current of high voltage; no hot bath or tonic produced results in any way comparable. She proceeded to give details of two patients on whom she had made many observations over a long course of treatment. One was a man the subject of angina, of heavy build and plethoric appearance, of whose blood pressure she had 59 records. The only relief he experienced from his pain was after a 10- or 12-minute high-frequency treatment on the condenser couch. After these visits the pulse always felt softer and more natural to the examining finger. In the other case, in a man 67 years of age, the story was similar.

Dr. ADOLF SCHOTT (Bad Nauheim) spoke of a case of severe angina pectoris, for whom no treatment, even nitroglycerine, did good. But in a comparatively short time after commencing diathermy the attacks were relieved. In another case of the same kind, however, diathermy did no good; it even started attacks, and only nitroglycerine brought benefit.

Dr. E. P. CUMBERBATCH said that in some experimental work at St. Bartholomew's Hospital it was found that the distribution of the heat applied seemed to be unaffected by changes in the voltage or by the frequency of the oscillation. He expressed his objection to the use of the term "high-frequency treatment of disease," as high-frequency currents were only of use in treatment if they produced heat in the body. The correct term to apply to such treatment was diathermy. The data required to be known were the ampèrage of the current and the temperatures produced. The result in circulatory disturbances was due to the heat generated, and what was important was the acceleration of the circulation through the tissues. One result on the blood of the application of heat was a lowering of its viscosity. Possibly the heating of the skin and the cutaneous nerve-endings produced a reflex vasodilatation of the blood-vessels of the interior. Some cases of intermittent claudication, he agreed, did well under diathermy, but others did not. The cases having hypertension which reacted best to diathermy were those in which renal disease was not present. Still, by applying diathermy to the kidney region specially, so as to promote the flow of blood through the organ, he had derived some success even in those cases.

Dr. G. B. BATTEN thought the idea that the sole effect of diathermy currents on the body was the production of heat was due to the fact that this effect was the easiest to measure. As sensitive instruments came to be devised in the future he thought it would become possible to measure other effects too.

Prof. RUSS and Dr. COTTON briefly replied.

SECTION OF MEDICINE.

AT a meeting of this Section, held on Jan. 24th, the chair was taken by Dr. H. THURSFIELD, Vice-President, and a discussion on

CARDIAC INFARCTION

was opened by Dr. JOHN PARKINSON, who said that it was now realised that this condition was of much more than pathological interest, since many patients might recover. A typical attack occurred in a man of 45 or more who was usually seized, while resting or engaged in normal exertion, with rapidly developing pain in the chest. The pain almost always included the region of the sternum and became intense in a very few minutes, extending into the arms, as often the right as the left, and sometimes into the neck and back. This dull, heavy pain lasted for hours, even up to three days, and its effects were shown by collapse or shock. The patient, although pale, cyanosed, and sweating, perhaps vomiting, might want to move about. The possibility of sudden death was present throughout. The pulse remained regular and might be slowed; the temperature fell during the attack and rose in the succeeding days. The blood pressure was low and might be below 100 systolic. A number of cases had a pericardial rub, but this usually appeared on the third or fourth day, too late to help in diagnosis. A marked leucocytosis succeeded the attack. The complications were sudden death, embolism (10 per cent.), and the ordinary congestive type of heart failure in some degree. It was thus clearly differ-

entiated from angina, which came on during exertion, immobilised the patient, lasted a few minutes only, and in which there was no shock, no dyspnœa, rarely vomiting, no alteration in pulse, temperature, blood pressure, or heart sounds.

As time went on, the speaker hoped, we should be able to establish the diagnosis in less typical and convincing cases. Variants on the type were: the patient who developed a rapidly-increasing series of anginal attacks; the patient who for two or three weeks had repeated and terrible attacks of pain lasting longer than typical angina; and the patient who manifested cardiac failure of the ordinary type with dyspnœa, but without much pain. Arterio-sclerosis was the underlying condition; cardiac infarction was not often related to syphilis nor most common in patients with high blood pressure; 50 per cent. of sufferers had had previous angina. In most there was no thickening of the superficial arteries, but arterio-sclerosis was suggested by a loud aortic second sound when syphilis and high blood pressure had been excluded. The largest artery of the body could now be inspected directly by X ray and the smallest by the ophthalmoscope. In cases of coronary thrombosis the aorta showed radiographically a prominent dense knuckle near the clavicle and a wide shadow. (These appearances were illustrated by slides.) Part of the mystery surrounding angina pectoris had been solved now that it was realised that, in a large proportion of cases, cardiac infarction played an important part as complication or cause. Sufferers from angina might develop it after a cardiac infarct or have a sudden exacerbation due to infarction, and might be better or worse after it. The essence of management was moral support and morphine. Amyl nitrite was valueless and to be avoided. The speaker had an impression that some of his patients had improved under digitalis, but it was important to avoid any abnormal rhythm, such as this drug might originate. Long rest was essential; the condition should be looked upon as an illness comparable to typhoid.

Pathology and Electrocardiographic Diagnosis.

Dr. D. EVAN BEDFORD said that he had collected, from records of the past five years, 83 post-mortem cases of cardiac infarction, usually due to coronary thrombosis. Coronary atheroma underlay 80 per cent., syphilis 10 per cent., and coronary embolism 5 per cent. Syphilitic aortitis occluded the coronary orifices, but never affected the front of the arteries. Embolism was usually a complication of infective endocarditis or intra-auricular thrombosis. There was often gross coronary atheroma when the aorta was healthy, and atheroma undoubtedly had a predilection for the coronary arteries, producing stenosis of their lumen. Thrombosis occurred at this narrow part, or at an ulcer, or else through rupture of the intima and the formation of a small dissecting aneurysm. The left artery was affected twice as often as the right, and the site of election was the first two or three centimetres of the left anterior descending branch. Ninety per cent. of the cases were males; this might be due to some sex difference in cholesterol metabolism, as the feeding of animals on cholesterol produced atheroma. Dr. Bedford showed slides illustrating the area of myocardium involved and the microscopical appearances. The complications were pericarditis, intraventricular thrombosis, rupture of the heart, aneurysm and hæmorrhage into the myocardium and pericardium. Old infarcts were a common pathological finding, showing that many patients survived. Many who died died because they would walk about within a week or two of the infarction; the fall of blood pressure was a natural safeguard against rupture and must be maintained. He had known cases diagnosed as hysteria because the pain lasted too long for ordinary angina. Various cardiovascular conditions might be confused with infarction, and the differential diagnosis from acute abdominal conditions was very difficult. The guiding points were the dyspnœa, the tachycardia, the radiation of pain to arm and jaw, and the history. Dr. Bedford then showed slides illustrating the electrocardiographic changes during and after an attack. In the acute stage there was deviation from the iso-electric level of the segment between the R wave and the T wave; often this went up in lead 1 and down in lead 3. The small ventricular waves were notched or splintered. The deviation of the RT segment was very characteristic. In the healing stage the T wave was inverted either in lead 1 or in lead 3, but not in both. It was usually flattened or inverted in lead 2.

Dr. CAREY COOMBS asked whether the condition was becoming more common, or merely more commonly recognised. Knowledge of it was most valuable in determining the site in many cases of cardiac pain. The distribution of pain in infarction was the same as that of mild angina, suggesting that the latter had its origin in the cardiac wall itself. Eighty per cent. of his cases of infarction fell into a "senile arterio-sclerotic" group, when hyperpiesis and chronic infections such as syphilis had been excluded. Seventy per cent. of his cases of anginal pain came into the same group. On the other hand, this syndrome was absent from cases of cardiac syphilis, and embolism was rare as a cause of infarction. He had frequently found infarction in association with arterial obstruction elsewhere; once with senile gangrene and four times with intermittent limp. Occasionally there was a definite familial incidence. Considering all these facts, he thought it would be agreed that the background of the condition was senile degeneration of the arterial tree, perhaps with special reference to the coronary vessels. He thought infection might act as a precipitating factor. The combination of pericarditis (which occurred in 17 out of his 40 cases), fever, and leucocytosis would be accepted as evidence of infection under any other circumstances. Seven of his cases had suffered from recent acute infections—e.g., pneumonia, facial erysipelas, and bacilluria.

Infarction due to Premature Senility.

Dr. G. HADFIELD said he had repeated Gross's experiments and confirmed his findings by injecting a radio-opaque mass into the heart post mortem. After the fourth decade a very definite change took place in the vascular supply of the heart which, from consisting of straight, fairly large trunks arranged in an orderly system of branches, became crowded with very many minute, closely and irregularly packed vessels, branching very unequally and tending to become tortuous. He showed skiagrams comparing the heart of a man of 75 or 80 years of age with that of a patient after a cardiac infarction, and remarked on the striking similarity. He suggested that in a case of ischæmic necrosis in a man of 55 we were dealing with a heart whose coronary circulation had reached a stage of senility not normally reached until 85. This type of circulation was precarious, especially if associated with a left-sided hypertrophy and in the presence of acute infection, which acted by lowering the blood pressure. Animal experiments had shown that to get the largest area of infarction it was always necessary to lower the blood pressure artificially. Three almost consecutive cases of infarction under his care had had pneumonia, diphtheria with pericarditis, and acute bronchitis respectively.

Dr. J. A. RYLE recorded the outstanding features of the 14 cases that had come to his notice in the last two years, 12 of them during the past 12 months. Age had ranged from 46 to 90; eight had been men and six women. All had been private patients, for, like angina, cardiac infarction was rare in hospital practice. Most of them had been energetic individuals; the series included a doctor, a general, a judge, a hospital sister, a district nurse, and three active business men. Six had had previous anginal attacks and four more previous evidence of cardiovascular disease. Two had been suspected of acute gall-bladder disease, owing to epigastric tenderness under the right rib and a slight subicteric tint which was not uncommon a few days after the attack. Three had vomited; 11 had had pyrexia and five a friction rub.

Equalisation and faintness of the cardiac sounds was an important sign; all had had low blood pressure, except one in whom the reading had gone up from 120 to 190. The pulmonary signs of cardiac failure had been very patchy. Interesting subjective symptoms had been worrying pain over the fourth cervical area, similar to that associated with diaphragmatic pleurisy, and a severe neuralgia in the back of the neck and occiput (four cases) which might be very persistent. Finally Dr. Ryle pointed out that John Hunter's first anginal attack, 20 years before his death, had undoubtedly been one of cardiac infarction.

Dr. B. T. PARSONS-SMITH agreed that signs and symptoms were unmistakable, and might be summed up as a status anginosus with coexisting cardiac and circulatory failure. In one type of case the infectious process matured insidiously and the myocardium accommodated itself; in another cardiac infarction followed acute coronary arteritis. In a third type coronary occlusion was an episode in a process of circulatory inefficiency and aggravated pre-existing symptoms. With these exceptions the cause of infarction was atheroma of the coronary vessels, and the disease ran a relentless course. In most cases belonging to the angina group death depended on the complication of cardiac infarction. Tachycardia served as a menace to the mechanical efficiency of the peripheral circulation and embarrassed the already prejudiced coronary supply. The rhythm might be altered, for instance, premature contractions might occur, or bradycardia or heart-block. Electrocardiographic evidence should be sought early, or important details might be missed. Anastomosis was normally free in the coronary circulation and increased with advancing years, but might perhaps be absent in some cases. On this might depend the prognosis of a case of infarction.

Dr. E. STOLKIND said that the diagnosis was still very difficult and was very important in order to differentiate cardiac infarction from true angina, now that sympathectomy was practised for the latter. He gave an account of an investigation he had made into the subject, and said he had traced 62 cases in the literature up to 1915.

Dr. PARKES WEBER pointed out that in infarction the acute pain might disappear in every part for short intervals; this differentiated it from the pain of any abdominal condition. He thought that Dr. Hadfield's analogy with senility was far-fetched, but the condition was exactly what was found in thromboangeitis obliterans of the legs.

Dr. T. J. HOSKIN agreed that amyl nitrite was detrimental and might produce vomiting. He did not think the electrocardiogram would ever be normal after a cardiac infarction; the area infarcted was bound to show somehow. In addition to rest and morphia, oxygen was useful where there was cardiac failure, and he had had some success with venesection. Most of his cases had been in male Jews.

Dr. T. W. DAVIDSON showed a specimen in which an old infarct had become calcified. It was the heart of a lunatic who had been 25 years in an asylum; he had led an active life and shown no symptoms before suddenly falling dead.

Dr. WEBER urged a search for bone in the calcified wall of the ventricle of this specimen. In his experience the protective calcification always went on to the formation of true bone.

Dr. PARKINSON, in reply to Dr. Carey Coombs's question, said that, if the duration of life were increasing, arteriosclerosis would be increasing, and so cardiac infarction would become more and more important. The patient who had a tachycardia of 100 or more without pain two or three weeks after infarction was one to watch. The tachycardia might be the herald of further complications. He did not agree that, in the present state of knowledge, a normal electrocardiogram could not be found after infarction.

LIVERPOOL MEDICAL INSTITUTION.

AT a meeting of this Institution held on Jan. 14th, Dr. J. C. M. GIVEN, the President, being in the chair, Dr. A. DINGWALL FORDYCE read a paper on the

Detection and Care of Rheumatism in Childhood.

Detection of the frank classical type of acute rheumatism, he said, is simple, but active rheumatism —of danger to the heart—is often present in children with the existence only of symptoms which are not at all striking. The fundamental inclination towards infection is a diathetic peculiarity which may be determined before or after birth, and which may lead ultimately to the exhibition of rheumatic symptoms as a result of endogenous infection by (probably) varying organisms of a similar group. Our main aim must be to prevent the development of such a constitutional tendency as will lead to a favourable field for bacterial infection. During the year 1927, 213 cases of rheumatism were dealt with in the out-patient department and in the wards of the Children's Hospital. One child died of rheumatic heart disease. In 71 cases the heart was permanently damaged without doubt when the child was first seen, and at the end of the year 97 children disclosed permanently damaged hearts. In 31 cases the condition of the heart was doubtful, and in 84 cases there was no cardiac affection. Rheumatic nodules were noticed in three cases. The intelligence quotient, taken during the quiescent or convalescent stage, was usually well above 80, the deficiency being mainly scholastic. The essence of correct care was physical and mental supervision for a prolonged period. For the poorer classes six months in a country hospital with school, such as that at Heswall, proved very valuable, after the initial condition had been dealt with in the city hospital, but to procure effective results a further prolonged period in a residential school was often essential.

Mr. FRANK JEANS read a note on

Statistics with Some Observations.

Certain observations, he said, were more valuable than statistics, e.g., one of Mr. F. J. Paul's, that a woman of 75 was not as old as a man of 75 from the point of view of a major operation. There was a statistical effect on an operator's morality, which showed itself in the rejection or inclusion of certain cases, subconsciously of course, which might affect his mortality. He thought that if an appendicitis was treated medically and the patient died because it was really an internal strangulation, it should figure as a death from appendicitis treated medically; and a death from pneumonia treated by operation in mistake for appendicitis should figure as a death from appendicitis treated surgically, because the patient was, if not statistically, actually dead. One point was of enormous importance. Now that a great deal of surgery was being done by practitioner-surgeons, it must be obvious that pure surgeons were getting an increasingly high percentage of difficult cases, and, therefore, if their mortality was as high as it was 15 years ago, this was no cause for depression. The practitioner-surgeon, who often admitted that he only did the easy cases, was more selective than the pure surgeon was allowed to be; comparison between the two classes of mortality was therefore impossible.

COVENTRY HOSPITAL SATURDAY FUND.—In the past year this fund raised a total of £29,000, which creates a "record," the previous year's figure having been £22,625. Of this total £11,000 was the produce of a carnival. Since the establishment of the fund in 1874 it has raised £256,000.

DUNDEE INFIRMARY.—The trustees of the late Sir James Duncan, of Kinnettles, have made a grant of £30,000 to this hospital. Of this sum, £24,750 is to be expended upon the erection and equipment of a dispensary; the remainder is to be devoted to the endowment of five beds.

Reviews and Notices of Books.

INTERNAL SECRETION.

The Comparative Physiology of Internal Secretion. By LANCELOT T. HOGBEN, M.A. Cantab., D.Sc. Lond., Professor of Zoology in the University of Cape Town. London: Cambridge University Press. 1927. Pp. 148. 10*s.* 6*d.*

THIS third volume of the new series of monographs dealing with comparative physiology, published by the Cambridge University Press, has been compiled by Prof. Hogben, who is an active experimenter, with critical judgment. In this monograph he has obviously been at pains to include only experimental results of proved value. The result is an excellent essay of moderate dimensions, which should be of much use to physiologists. Starting with a chapter on chemical coördination, where the author discusses the precise sense in which he considers the term internal secretion should be employed, he passes on to the question of adrenalin and neuro-muscular coördination. In Chapter III. the relationship of internal secretion to chromatic function is fully dealt with. Prof. Hogben points out that perhaps the most conclusive evidence of internal secretion in the field of comparative physiology is seen in the control of colour response in amphibia. The rôle of the pituitary secretion in influencing the degree of expansion or contraction of the melanophores can be demonstrated by injection and ablation experiments. The pituitary injected frog is a dark adapted frog, whilst, on the other hand, injections of adrenalin induce a contraction of the melanophores. The part played by endocrine factors in regulating secretory processes in the body is described in Chapter IV. This includes a discussion of the regulation of the digestive processes, and also of a hypothesis recently put forward by Dixon and Marshall to account for the phenomena attending the termination of pseudo-pregnancy in the mammal, when, it is suggested, an ovarian-pituitary mechanism comes into play. There are also chapters on the relation of internal secretion to vasomotor regulation and endocrine factors in metabolism, the latter being discussed under three headings: the relation of the thyroid to basal metabolism, the relation of the pancreas to carbohydrate metabolism, and the functional significance of the parathyroid glands. In the last chapter the rôle of the ductless glands in developmental processes is dealt with. There is a very good account of the progress which has been made in relation to thyroid function in this connexion, and also of the experiments carried out to demonstrate the part played by the pituitary in the timing mechanism in amphibian metamorphosis.

RHEUMATISM AND GOUT.

Aspects of Rheumatism and Gout. Their Nature, Prevention, and Control. By LLEWELYN JONES LLEWELLYN, M.B. Lond., Consulting Physician, National Hospital for Rheumatic Diseases, Bath. London: William Heinemann (Medical Books), Ltd. 1927. Pp. 295. 10*s.*

Dr. Llewellyn, in this, his latest contribution to the study of rheumatism and gout, reveals a wide knowledge of the publications of others on the subject, whether these are based on speculation or genuine research. His own theories are in many respects unconventional. His opening chapters deal with diathesis and describe clearly the varying degrees of importance which have been given to it at different times as a factor in ætiology. He then develops the theory of "autonomic-endocrine-imbalance," and throughout the book it is clear that Dr. Llewellyn considers infection of subsidiary importance to glandular deficiencies. In his opinion endocrine disturbance is the cause of the vasomotor instability which Pemberton and his co-workers believe to play a leading rôle in the pathogeny of both atrophic and infective arthritis. One interesting chapter on the pre-rheumatic state in childhood deserves to be widely read. It gives an unmistakable clinical picture which is unfamiliar to many practitioners; if they learn to recognise it as typical, Dr. Llewellyn holds that in many cases disastrous consequences may be avoided. He emphasises the urgent need for preventive treatment, and complains that at present nearly all medical effort is applied to preventing the recurrence rather than the onset of the disease. The chapters dealing with pitfalls in diagnosis are perhaps the best in the book. Here the author is writing from personal and very wide experience as a spa physician, and these pages are full of sage advice.

The period of indiscriminate extraction for supposed dental origin of rheumatic disease is happily passing, but the final chapter on oral sepsis in relation to arthritis contains sound teaching. Even those whose views on rheumatic disease differ widely from those set out by Dr. Llewellyn will gain by studying the fruits of his ripe experience.

EPIDEMIC ENCEPHALITIS (ENCEPHALO-MYELITIS).

By LEO M. CRAFTS, B.L., M.D. Harv., formerly Dean and Professor of Nervous and Mental Diseases, Medical Department of Hamline University, Minneapolis, Minn. Boston: Richard G. Badger. 1927. Illustrated. Pp. 237.

THIS book is mainly a record of cases of epidemic encephalitis which Dr. Crafts has met with in his practice. About half the volume is devoted to case-reports; these would have made more interesting reading if they had been grouped under descriptive headings. Based mainly on these cases the author has written an account of the disease. This may be useful to the American student and general practitioner desirous of obtaining general knowledge on the subject, but it will not convey much new information to the practising neurologist. The proof-reading has been carelessly done. "Naso-phatyngeal" for "naso-pharyngeal," and "Trumbull" for "Turnbull" are illustrative examples; while the sentence on p. 65, "But will soon show the emergence of some of the above making a congerie at once clearing to the diagnosis," seems a departure from the "direct and ordinary English" in which, the author tells us in the preface, it has been his purpose to present his material.

CLINICAL CASE-TAKING.

By GEORGE R. HERRMANN, M.D., Ph.D., Assistant Professor of Medicine, Tulane University, New Orleans. London: Henry Kimpton. 1927. Pp. 90. 6*s.* 6*d.*

THE sudden change from the cold precision of the laboratory to the more haphazard methods of the bedside is often liable to offer opportunities for slackness to the unenterprising or tired student. He finds supervision relaxed, investigation less exact, and the whole field of medicine seems so vast that he succumbs to the temptation to take things easily. To combat this attitude a good guide to case-taking which endeavours to present a "case" with somewhat of the exactness of a scientific experiment is valuable. The business of the clinical clerk is to obtain and set down diagnostic data, and here he will find the necessary methods presented in an intelligible form. First the administrative data, so essential to an institution, then the story of the present illness, working back to the social history and the history of previous complaints, all are set out clearly. The physical examination is next developed in detail, laboratory examinations are indicated, and in the supplement are placed notes on diagnosis, abbreviated histories, abstracts, and progress notes. Dr. Herrmann's book is intended to supplement the "Methods in Medicine," the manual of the medical service of George Dock, and while all allowances are made for the special application of this book to the work at Tulane University, it certainly makes a larger, if not an international, appeal.

MAX VON PETTENKOFER.

His Theory of the Ætiology of Cholera, Typhoid Fever, and other Intestinal Diseases.. By E. E. HUME, M.D. New York: Paul B. Hoeber. 1927. With two portraits and six other plates. Pp. 142. $1.50.

Pettenkofer (1818–1901) got his start in life by being appointed professor of medical chemistry in the University of Munich at a salary of £60 a year with two measures of wheat and seven measures of rye. After a career of the greatest distinction in all branches of hygiene, he shot himself on Feb. 10th, 1901. Dr. Hume deals particularly with his views on the causation of cholera and typhoid fever. Pettenkofer held that the immediate cause of cholera was an *x* which he at once identified with the cholera vibrio when, years later, that was discovered by Koch in 1883. But he would have nothing to do with the idea that cholera could be caught by one person from another. He held that the comma bacillus had become innocuous when it was passed in the stools and could regain its virulence only by developing for a time in foul soil which was neither too wet nor too dry. Hence his famous association between a fall in the ground water and an epidemic, to which his statistical friends attached a probability of 36,000 to 1. Now that hygienists are beginning to think once more that there is something more than the bacillus in an epidemic, the tale may well be read again and pondered over. Dr. Hume tells it pleasantly enough, though some curious mistakes (p. 6 "Marsch," p. 20 "pyroxalic acid," and p. 22 "zinc content of the air") make one a little doubtful whether he is altogether reliable on technical details. There is an ample bibliography of 285 items by and about Pettenkofer.

INTRODUCTION TO PHYSIOLOGICAL CHEMISTRY.

By MEYER BODANSKY, Ph.D., Associate Professor of Physiological Chemistry, University of Texas. London: Chapman and Hall, Ltd.; New York: John Wiley and Sons, Inc. 1927. Pp. 440. 20*s*.

IN this book of moderate size Dr. Bodansky undertakes the difficult task of writing for students starting the subject, and also for those who wish to obtain information in specialised branches. On the whole he has succeeded well, and one good point is that this volume is one of the few elementary text-books giving an adequate series of references. The ground covered is very much the same as that of most other text-books on biochemistry. The first chapter or introduction is devoted to a very brief consideration of physical chemistry which could have been considerably extended with great advantage to the elementary reader. A more detailed description of the hydrogen electrode, for example, than that which appears on p. 19, together with a simple diagram would have been of great assistance to the student. The account of Donnan's membrane equilibrium theory is so condensed as to be difficult to follow.

A series of chapters on carbohydrates, fats, and proteins comes next. One novel feature in the section on proteins is a concise account of the views of the late Dr. Jacques Loeb. We believe that this is the first time that his work on the stoichio metric combining powers of proteins with acids, &c., has ever been explained in an elementary text-book. The chapter dealing with enzymes is rather nebulous and does not give any practical methods of estimating the activity of these substances. In the section on hæmoglobin the author has taken great care to incorporate the views of the most recent workers, such as J. Barcroft, M. L. Anson, and A. E. Mirsky, but he has rather neglected the work of the earlier investigators. For instance, some of the more stable derivatives of hæmoglobin, such as hæmatin, are by no means adequately described. An interesting section on physiological oxidations and a series of four chapters dealing with metabolism follow and the rest of the ground is adequately covered.

This volume will be of the greatest value to students of biochemistry, both as an elementary text-book and as a work of reference.

JOURNALS.

JOURNAL OF PATHOLOGY AND BACTERIOLOGY. Vol. XXXI. No. 1. Pp. 1–139. January, 1928.—Histamine and Leucocyte Emigration, by R. T. Grant and J. E. Wood (London). It seems very probable on general grounds that the phenomena of inflammation are caused by some product of injured tissues; histamine is known to cause dilatation of the small blood-vessels and increased permeability of their walls, but, as the authors show, it is not responsible for the emigration of leucocytes.—A Keratitogenous Virus of Pulmonary Origin, by J. R. Perdrau (London). A virus causing keratitis, but not encephalitis, in rabbits is found in a considerable proportion of human pneumonic lungs.—The Histology of Post-vaccinal Encephalitis, by J. R. Perdrau (London).—Variations in the Leucocyte Count upon Single and Repeated Injection of Quartz and of Indian Ink Particles, by A. R. Elvidge (Montreal). Such injections cause a leucopenia, followed by a leucocytosis; a second injection during the leucocytosis does not produce a leucopenia and this reaction is not specfic.—Proliferation of Endothelium on the Liver in Experimental Venous Stagnation, by C. Bolton and W. G. Barnard (London). In venous obstruction produced by partial occlusion of the inferior vena cava above the diaphragm the endothelium on the surface of the liver proliferates into buttons, knobs, and polyps without anything which may be called an inflammation.—The Distribution of Tuberculous Lesions in Man and Other Primates with an account of the Lymphatic Glands and Vessels of the Thorax and Upper Abdomen, by H. H. Scott and J. Beattie (London); annotated on p. 198.—The Determination of the Rate of Antibody (Precipitin) Production in Rabbits' Blood by the Method of Optimal Proportions, by H. R. Dean and R. A. Webb (Cambridge). The course of the reaction can be followed well by finding the mixture of antigen and antibody which flocculates most rapidly.—The Cells of Peritoneal Exudates in Guinea-pigs, by L. J. Witts (Cambridge). Working with intravitam and supravital staining the author finds that silver nitrate brings out the cells in the order endothelium, neutrophiles, lymphocytes, eosinophiles, macrophages. These last are of the clasmatocyte type, into which monocytes probably change on leaving the blood stream.—A Modification of McIntosh and Fildes' Anaerobic Jar, by G. S. Wilson (London). An engineers' pattern which costs 12 guineas.—Adenomata of Pancreatic Islet Tissue in the Pylorus and Duodenum, by M. J. Stewart and S. J. Hartfall (Leeds). Heterotopic pancreas is not uncommon, but nodules composed of islet tissue do not seem to have been recorded before.—The Stability of Schick Toxin, by A. T. Glenny, C. G. Pope, and H. Waddington (Beckenham). A borax + boric acid + sodium chloride mixture preserves diluted Schick toxin quite satisfactorily.—A Strain of *B. diphtheriæ* showing Unusual Virulence for Guinea-pigs, by W. Mair (London). A uniquely virulent strain which could not be completely neutralised in vivo with any quantity of antitoxin; death could be prevented, but suppurative lesions still occurred.—Difficulties in the Agglutination of Hæmolytic Streptococci, by F. W. Andrewes (London). Two sorts of colonies must be recognised; the smooth glossy ones give only group agglutination; for specific results the rougher matt colonies must be used.—The Treatment of Relapses in Experimental Trypanosome Infections, by C. H. Browning and R. Gulbransen (Glasgow). After repeated relapses cure may be ultimately obtained with the same trypanocidal drug and without increasing the dose.—Obituary notices of J. W. Dawson and Adrian Stokes.—Proceedings of the Society.—Books received.

THE LANCET.

LONDON: SATURDAY, JANUARY 28, 1928.

THE DIETETIC VALUE OF MILK AND MILK PRODUCTS.

THE exceptionally high dietetic value of milk for the human dietary has been emphasised lately by the work of Dr. CORRY MANN and of Dr. W. CRAMER. The preliminary report by Dr. J. B. ORR on a large scale test carried out on school-children in seven cities and towns in Scotland and in Belfast, which we publish in this number, adds further confirmatory evidence. There is nothing surprising or revolutionary in the idea that milk is a most useful food for the growing child. The vitamin content is not, of course, the only factor that confers upon milk and milk products their dietetic value, which was recognised before the discovery of vitamins; and our new knowledge of the existence of these food accessory factors has justified a common belief. The earlier writers on dietetics, however, thought merely in terms of quantity. An adequate diet in their view was one which provided for an adequate intake of protein and of total calories. The study of the chemistry of proteins which revealed these substances as being built up of amino-acids has made it clear that all proteins are not dietetically equivalent. Broadly speaking, the body requires for its well-being to be supplied in the food with all the amino-acids of which its cells are built up; a protein which contains all these amino-acids is therefore of a higher dietetic value than one in which some essential amino-acids are missing. Gelatin is an example of a protein of very low dietetic value, since many essential amino-acids are missing in its make-up; it is therefore impossible to live on a diet in which the protein is supplied entirely in the form of gelatin, and such a diet has to be supplemented by the addition of proteins of a very high dietetic value. The proteins of milk—casein and lactalbumin—or of meat are examples of proteins of a high dietetic value, since they contain all the essential amino-acids. In an intermediate position are the proteins of bread which are completely deficient in only one essential amino-acid (lysin) and partially deficient in another (tryptophane). The mineral constituents are another important factor in the consideration of a diet, especially where the growing organism is concerned. The growing child has a special requirement for calcium and phosphates for the building up of bone. Recent work in rickets has shown that these inorganic elements must be supplied in the diet not only in adequate amounts but also in definite proportions. Most articles of food are poor in calcium; milk is especially rich in calcium and contains calcium and phosphates in the proper proportion. A pint of cow's milk contains one gramme of calcium, more, in fact, than is contained in a pint of lime-water. VOIT has calculated the calcium requirement of the growing child as one-third of a gramme per day; such a requirement would be covered by the consumption of 7 oz. of cow's milk. If it had to be covered by the consumption of bread or of eggs it would require 1000 grammes of bread or 15 eggs. Such a diet is unsuitable for bone growth because, apart from any other consideration, it furnishes the required calcium with a large excess of phosphates, which would be harmful. Milk is also relatively rich in vitamin A, which is associated with the fat and is therefore absent, or greatly diminished in amount, in separated milk. It also contains a considerable amount of vitamin B. It does not contain vitamin C.

If we compare the dietetic value of milk with that of another staple article of diet—bread—we find that, as already stated, the proteins of bread are not of the same high dietetic value as those of milk. Moreover, bread is poor in calcium and contains this element with a large excess of phosphates, while so far as vitamins are concerned, white bread contains neither A, C, nor, as appears now to be generally agreed, B. The dietetic value of bread lies in the fact that it presents the bulk of the chemical energy required in a form which is cheap, palatable, and not readily perishable. We may say that bread stands for quantity, milk stands for quality. What is true for milk applies also to its products, cheese and butter. Cheese contains the protein casein, of a high dietetic value, in a very concentrated form, together with a certain amount of vitamin B. Butter is rich in vitamin A. Both contain less calcium than milk but are still richer in calcium than most other articles of diet. As the calcium requirements for growth become less urgent so the diet changes from milk to cheese and butter. It is now readily seen why milk and its products are of such high dietetic value. Their addition to a diet corrects most dietetic deficiencies except a deficiency of vitamin C which can be supplied by fresh fruit and vegetables. A diet therefore which is built around a basis of bread or cereals and milk or its products is economically and dietetically sound. The point has been very neatly put by no less an authority than GRAHAM LUSK who, in deploring the general ignorance concerning the elementary facts of dietetics says: "Few of those who eat in restaurants realise that the greater quota of nourishment which is brought to them lies not in the specific dish served but in the bread and butter which is ostensibly presented as a gift." That cereals and milk or its products represent the basis of our diet has, of course, been the experience of mankind, and if, to-day, the question of a sound dietary has become a problem for serious consideration, it is because the consumption of milk and its products has fallen into disuse, partly for economic reasons, partly through ignorance, and partly as the result of the teaching of faddists who take a one-sided view of dietetic problems. The remarkable improvements obtained in children both by Dr. CORRY MANN and by Dr. ORR by the addition of milk to their diet, is evidence not only of the high dietetic value of milk but also of the inadequacy of the diet on which the children had been kept. From this point of view the investigation of Dr. ORR is of special value because it applies to children who live in their homes. The result is a striking commentary on the glib statement which one hears and reads so frequently that on the whole the dietary of the people in this country is adequate.

It is also clear from these considerations that even separated milk is of high dietetic value especially to growing children if the child is kept on an inadequate diet. For the addition of separated milk will compensate for an inadequate supply of calcium, for a deficiency of vitamin B, and for the presence of proteins

of low dietetic value in the basal diet. But it would be a serious mistake to argue that separated milk is as good as full milk, unless butter happens to be given in the diet. There is abundant evidence in the literature, beginning with the well-known paper by Dr. C. E. BLOCH, of Copenhagen,[1] to show that the absence of milk-fat in the diet leads to serious impairments of health—not only in children but also in adults. There is also the evidence of Dr. CORRY MANN'S investigation, where the group of children receiving butter did nearly as well as the group receiving full milk. If this difference has not yet appeared in Dr. ORR'S investigation it is due to the fact that the ill-effects resulting from a deficiency of milk-fat take a much longer time to appear and that they are not so readily reflected in the height and weight of the children, which form, after all, a superficial criterion of the general state. It is known from experiments that animals can grow to their natural size on a diet deficient in vitamin A, but are nevertheless inferior to a normal healthy animal in their general vigour and in their greater susceptibility to infections, especially of the respiratory tract. H. C. SHERMAN has, in fact, recorded this effect in an experiment in which separated milk was used.[2] The further reports of Dr. ORR'S investigation, which is being carried out under the authority of the Scottish Board of Health, will be awaited with the keenest interest. The importance of this investigation as well as that of Dr. CORRY MANN cannot be overestimated. The Medical Research Council, which was responsible for Dr. CORRY MANN'S study, and the Scottish Board of Health have rendered an important service to the community in having supported work which could not have been initiated satisfactorily by a private individual; we should like to see a more extended investigation covering the whole period of childhood and carried out in institutions. Sir GEORGE NEWMAN, in his recent report On the State of the Public Health, writes: "When it is realised that little more than a quarter of a pint is the average daily consumption of milk in this country at the present time, some conception can be formed of the inadequacy of the amount of this most valuable food which its children are receiving, and of the improvement in their growth and vigour which might certainly be secured by an adequate increase in its consumption. . . ." Dr. CRAMER, in drawing the same conclusion, has shown that not only the consumption but also the supply of milk is inadequate. The dairying industry complains that, under the present conditions of an inadequate demand, it cannot dispose of all the milk it produces, and that for its salvation as an industry it requires an increased demand. Is this really a problem the solution of which surpasses the wit of man?

NOMENCLATURE.

HUMAN thought is always a little in advance of human language, and since Adam's time man has continually been engaged on finding names for things as he slowly disentangled them from one another. And with that innate passion for security and certainty which he has had for at least as long, man has gone on defining and naming in the glorious hope that finality is to be found with the other ingredients of the golden age just round the next corner. Such a faith is altogether admirable in that it makes for clear thinking and clear writing in the descriptions of our discoveries. But in its eschatological form it is, of course, wholly illusory; a complete and immutable system of names and definitions presupposes a state of completion of human knowledge which means an end of progress so repugnant that no lively mind can contemplate its possibility.

Nomenclature then is not a question of absolute truth. Some people think it is; they take it too seriously and fall into the trap of giving definitive names, true to-day, false to-morrow. But it is a matter of practical importance, and no doubt, as Dr. E. WARD suggested in our columns last week, most doctors do not take it nearly seriously enough. In medicine obscurities and difficulties of names and definitions seem to arise, roughly speaking, in three ways—from realising that two things which were thought to be the same are really different, from finding that apparently dissimilar things are really alike, and from general ignorance of the nature of the thing. The old controversy about the cause of "sunstroke" was solved by the discovery that excess of actinic rays causes "sunstroke" and a hot moist atmosphere causes "heatstroke"; "sunstroke" is still used as including heatstroke, and there is a real gain in giving up the term and talking of "insolation" instead. Similarly the difficulties about "shock" have largely disappeared since it was realised that immediate shock, of the nature of a severe faint and due to overstimulation of the central nervous system, is quite different from secondary shock, mainly an anhydræmia and caused by the absorption of histamine-like bodies from injured tissue. Examples of misleading differentiation are mostly pathological, and it is perhaps mainly from the point of view of the elementary student of general pathology that it is confusing to call what is essentially the same thing "pus" "caseous material" and "gummatous stuff" under different circumstances, or to speak of an "infarct" in the spleen and "softening" in the brain. The discovery of the tubercle bacillus revealed an underlying similarity in a great diversity.

It is to examples of these two classes of confusion that, we believe, it would not be difficult to apply effective and useful consideration, possibly by such deliberate means as an ad hoc committee. But it is another matter to deal in the same way with confused mobs like "rheumatism" or "eczema" in which only a few small groups have shown any signs of standing together on a basis of substantial identity. The useful definition of a disease may be ætiological—e.g., typhoid fever—or anatomical—e.g., cirrhosis of liver—or purely symptomatic—e.g., epilepsy: all such criteria are, in the final sense, provisional, but they do very well in practice. But when nothing is known about the cause, little about the morbid anatomy and the symptoms are various, it is difficult to see how much progress can be made with names and definitions. Yet the attempt is, we believe, worth making: if anyone is going to define "constipation" he will have to acquaint himself first with all that is known or suspected about it, and he would be a fuller man even if, as is likely, the profession declined to adopt the definition he finally reached. And an inquiry into the meaning of "rheumatism" will in one way or another repay all the work which can be put into it. But it would be unwise to expect too much from such a committee as Dr. WARD proposed in our correspondence columns; arbitrary definitions based on grossly inadequate knowledge would be worse than useless and names can be invented usefully only when there is something definite to identify. Patient inquiry will solve many of the present puzzles. There is a famous picture of Adam standing affectionately

[1] Journal of Hygiene, 1921, xix., 283.
[2] Sherman and Smith: The Vitamins, 1922, p. 197.

among the horse, cow, cat, and dog, and so on, for which he had easily found names, and looking a little doubtfully at an unfamiliar crowd of elephants and crocodiles and the like waiting for their titles; they got them in the end.

A NEW CHAIR OF PUBLIC HEALTH.

THE establishment by the University of London of a chair of public health, tenable at the London School of Hygiene and Tropical Medicine, is both generally an excellent departure and in special relation to the School is of real import. Only recently we had to chronicle at the School the institution of new departments of bacteriology and immunology under Prof. W. W. C. TOPLEY, and of epidemiology and vital statistics under Prof. M. GREENWOOD. When these things are recalled in connexion with the facilities for clinical and pathological study offered by the Seamen's Hospital Society we see that the students of the School have open before them opportunities which it would be difficult to over-estimate for carrying on the development of public health work in this country and overseas. Thus it is of prime importance to secure the right man for the chair. The governing body of the School have adopted a provisional scheme to come into force upon the new appointment, under which the broad practice of preventive medicine, the appropriate technique of sanitation, and the principles of official administration will receive parallel attention, so that the control of disease, both infectious and non-infectious, can be exemplified by practical measures, by scientific hygiene, and by much needed instruction in the way to secure full coöperation between health authorities and medical practitioners.

The applications of candidates for the new chair must be received by the Academic Registrar, University of London, South Kensington, S.W. 7, not later than the first post on Feb. 16th, a date that is near at hand; and it is understood that the elected man, though his appointment may not take effect until the beginning of 1929, will be asked immediately to take a seat on the School Council, and to assist in the organisation and equipment of his own special work. While the general supervision of the Director of the School, Dr. ANDREW BALFOUR, will remain, and while matters of broad policy and finance will be outside the professorial duties, the man appointed will bear a heavy responsibility which is not directly represented in a salary of £1500 per annum—in saying which we do not forget certain compensations which he will obtain. The work is of the highest importance both practical and academic, and the professor will have unequalled opportunities for public service, for the scope of his influence will be Imperial, and, indeed, international.

INTERNATIONAL CONGRESS OF OTO-LARYNGOLOGY. As we have already announced, this congress is to be held at Copenhagen from July 30th to August 1st. Among the subjects to be considered is the Anatomical Structure of the Ear and its Influence on the Course of Suppuration of the Middle Ear, on which a discussion will be introduced by Prof. Georges Portmann (Bordeaux) and Prof. J. Mouret (Montpellier). Messrs. Bennett, 66, Haymarket, London, S.W. 1, have been appointed by the Danish Committee to arrange excursions, and will shortly send out particulars to all who have joined the British Committee. The hon. secretaries of this committee are Mr. J. S. Fraser (Edinburgh), and Mr. F. W. Watkyn-Thomas and Mr. Lionel Colledge (London), to whom inquiries should be addressed. Dr. H. V. T. Borries, 10, Christian IX.'s Gade, Copenhagen K., is in charge of the arrangements for the anatomo-pathological museum and Dr. F. Norsk, 3, Nytorv, Copenhagen K., is arranging an exhibition of instruments. They invite contributions and applications should be made as soon as possible.

Annotations.

"Ne quid nimis."

OUR PRISON POPULATION.

THE Prison Commissioners' Report in former years has contained an Appendix of extracts from the annual reports of Governors, Chaplains, and Medical Officers. The extracts were frequently illuminating, and it is a pity that the Commissioners' Report for 1926, just issued,[1] omits it. There is, however, as usual, plenty of interest in the Medical Commissioner's contribution to the Report. The old difficulty of dealing with mentally defective prisoners under the Act of 1913, which arose from the statutory insistence upon knowledge of the defective's early history, has been partially removed by the amending Act passed at the end of last year. But it is clear that, although the administration of our insanity and mental deficiency statutes enables us to eliminate from the prison population large numbers of persons unsuitable for prison discipline, there is still much to be done. There remains a residue of non-certifiable cases which medical opinion must regard as improperly placed in a prison environment. This subnormal group includes the simple feeble-minded and the border-line prisoner "whose offences are due to their low intelligence and high suggestibility and who are relatively incapable of social rehabilitation on account of their low mentality." The group is defined to include mental defectives of congenital origin with or without epilepsy, persons in an imperfectly developed state of insanity, those who are senile or mentally weak after an attack of insanity, the weak-minded whose condition is due to alcoholic excess, and those whose condition cannot be attributed to any definite cause. Arrangements have been made for reporting these cases and, if the term of detention is a month or more, transferring them to special prisons where they can be segregated and suitably employed under modified discipline. It is, of course, unfortunate that their detention cannot be continued beyond the term of their sentence, but, on their discharge from prison, they are brought to the notice of the local agent for the Central Association of Mental Welfare. If the nation had regard to the economy and the mental improvement which might follow if a more permanent segregation could be authorised by Parliament, it is hard to believe that the law would not be speedily changed. These are cases which are unemployable in the conditions of life outside an institution, though there is a capacity for some simple manual employment under supervision. The Medical Commissioner gives particulars of 77 men and 29 women of this type. The commonest offence among the men was theft or receiving; amongst the women it was drunk and disorderly behaviour; the other offences vary greatly in gravity. One of the men had 54 previous convictions; one of the women had 109.

Two years ago (in the Report for 1924) the Medical Commissioner referred to the treatment of prisoners' teeth. He mentions this point again now in connexion with inmates of Borstal institutions; he is able to record that special arrangements have been made not only for the care of teeth but also for the correction of errors of vision and the cure of deformities or other conditions which prevent the Borstal boy or girl from receiving full benefit from training and which hamper their prospects of employment afterwards. There were five suicides in local prisons in England in 1926; this is not serious in view of the marked increase in suicide recorded in the criminal statistics for 1925 as occurring since the later stages of the war. Perhaps the most important topic in the Medical Commissioner's observations is the prevalence and effect of encephalitis lethargica. The disease has been studied over the two-year period from April, 1925, to the end of

[1] Cmd. 3003. H.M. Stationery Office. 9d.

March, 1927. No case of its onset in any prison or Borstal institution occurred, but 72 cases (65 males and 7 females) were noted amongst remand and convicted prisoners. Half of these cases were classified as "definite," the disease being established either from known early history or from typical subsequent condition. The remaining cases were classified (in almost equal proportion) as "probable"—i.e., where the history is indefinite but the mental and physical condition leave little room for doubt—and "suspected" where the existence of the disease is distinctly suggested. In only 53 out of the 72 cases did the attack of encephalitis occur before the age of 18; thus only two-thirds would have come within the new definition of "mental defectiveness" in Section 1, Subs. (2) of the 1913 Act as recently substituted by the amending Act of 1927. In 54 out of the 72 cases imprisonment either had no harmful effect or actually produced an improvement; the residue included one person insane on admission, another reported to the court as insane and cases which either deteriorated or got no benefit from prison life. The Medical Commissioner is careful to point out that, while the disease is serious and can at times have serious sequelæ, the after-effects are of all degrees of intensity; it cannot, he thinks, be logically contended that a person who has had encephalitis is thereafter necessarily immune from the consequences of his criminal acts.

THE WELLCOME RESEARCH LABORATORIES, KHARTOUM.

As soon as Lord Kitchener had reconquered the Sudan in 1898 he established the Gordon College as a boarding-school where secondary education could be given to picked native boys and other boys of African and Eastern race to equip them to take part in the political administration and the education of the country. Inevitably the College became the headquarters of education all through the Sudan, and gathered under its roof, besides its own departments, a number of kindred and indispensable organisations of which the best known to our readers is the Wellcome Tropical Research Laboratories. The year 1926, according to Major R. G. Archibald's report, incorporated in the Report and Accounts of the Gordon Memorial College Fund for that year, was the busiest since the foundation of the laboratories, as closer coöperation with the Government enabled a greater number of examinations to be carried out. The bacteriological section is to be removed shortly to new buildings near the Civil Hospital and the new Kitchener School of Medicine, where its usefulness will be still further extended. Among its activities in the year under review were 7510 routine examinations. One day in the week is set aside for syphilis tests, of which Kahn's precipitation test is still the most popular. An epidemic of enteric fever in the neighbouring city of Omdurman threw much extra work on the staff, who, in addition to examining a quantity of material, manufactured prophylactic and therapeutic vaccines on a large scale. Doses of cholera vaccine sufficient for 12,000 individuals were prepared for the protection of Sudanese Muslims making the pilgrimage to the Hejaz, all of whom are now inoculated. A serious outbreak of rabies in the southern provinces necessitated the preparation of 2000 doses of antirabic vaccine; the virus was sent down from the Antirabic Institute in Cairo and maintained by passage through rabbits. Work has been done on the investigation of the sources of well pollution throughout the country, a most important activity in a land where wells are the only supply for the bulk of the population. Another piece of research is that directed against bilharzia, and in this the staff are assisted by a brigade of intelligent natives who have been trained to locate and destroy the mollusc which acts as the intermediate host. The examination of several hundred cultures of soil bacteria has established that black arm disease of the cotton plant does not originate in the soil. The training of native laboratory assistants for hospitals in outstations is one of the latest additions to the activities of the centre. As well as carrying out their arduous duties, the staff have contributed six papers between them to various scientific journals.

The chemical section has for the last few years been chiefly engaged in soil and fertiliser investigations, in connexion with the rapid cotton-growing development on the Blue Nile. Other questions that have been referred to the section from time to time have been the Government contracts for sugar and petrol, the analysis of alcoholic liquors at the high local temperature, and the standardisation of the liquid rotl (pound). The Atbara laboratory busies itself with railway problems, such as the examination of water and fuel, the cause of priming in boilers, the prevention of scale, and the proofing of rolling-stock against fire. The staff of the section found time to publish four papers during 1926.

The entomological section have no lack of pests on which to make war, and some of their enemies at present are cotton-destroying termites, thrips, bollworm, and locust. The interesting fact has been established that the gregarious locust so destructive to crops is evolved by suitable climatic conditions from the solitary and sedentary *Schistocerca flaviventris*, and this discovery should prove of considerable economic importance. The Director recommends arsenite of soda as a preservative of timber against white ants. In addition to these sections, geological and antiquities sections flourish, and there is a natural history museum. Sub-laboratories have been established for some time at Atbara and in the rich irrigated belt of the Gezira. The future of the Sudan, which promises to be so prosperous and so important for the cotton industry of this country, will probably owe as much to the energy and initiative of this scientific foundation as it will to any department of the Government, which is fortunate to have the coöperation of so admirable a service.

THE APPARENT INCREASE OF CANCER.

WHATEVER may be its explanation, there has been an apparent increase of cancer during the last decade or two, and the general public is beginning to take alarm about it. In another column Dr. D. F. Shearer marshals his figures to show that the reported increase of death is only apparent, and that when proper allowance has been made for the effect of better diagnosis and more accurate certification there is nothing left which cannot be explained by a change in the age-distribution of the population. It is open to anyone to check his calculations, for his figures are taken from the annual reports of the Registrar-General, although he does not appear to be familiar with Dr. T. H. C. Stevenson's analysis in the 1924 report. Individual study of these figures is, of course, very laborious, and Dr. Shearer has limited himself to a comparison between two isolated years 1913 and 1925; very probably he would be the first to admit that a better idea of the general trend of the death-rate would be given by taking a continuous series of years, or by comparing two periods of five years or more, especially in the case of relatively uncommon sites. This has been done by Dr. Stevenson first for the series of years 1897–1911 (R.-G.'s annual report for 1917) and more recently (R.-G.'s statistical review for 1924) for the two decades 1901–10 and 1911–20; with these are compared the single year 1924, which is only one year less recent than the year chosen by Dr. Shearer, and the general result of taking 1924 and 1925 is the same. Dr. Shearer seems to think that Dr. Stevenson's conclusions were based for the most part on crude death rates, but although two tables in the latter's earlier analysis did employ crude death-rates at sites (for reasons explained) his general conclusions were confirmed by standardised values; and in the later report all the tables are based either on standardised rates or on rates at age-groups. When Dr. Shearer writes "the error that may arise from the use of

crude rates is well shown in the case of the tongue in the male. Using crude rates, cancer of the tongue rose between 1913 and 1925 from 56 to 63 per million living, standardisation shows that in fact cancer of the tongue had fallen from 70 to 63 per million living "—he is doing Dr. Stevenson an injustice, for in his 1924 report (Table XXXIX., p. 58) the latter gives the following standardised death-rates per million at all ages for cancer of the tongue—

1901–10.	*1911–20.*	*1924.*
43	51	48

which show the recent tendency to decrease that Dr. Shearer points out. The absolute differences in the rates quoted by Dr. Stevenson and Dr. Shearer are due to different standard age-distributions adopted in standardisation, but this does not affect the agreement in the general trend. With regard to Dr. Stevenson's grouping of the sites into "accessible" and "inaccessible" Dr. Shearer calls this a distinction "of opinion and not of statistical fact." The classification was based on reports of 52,420 cancer deaths in the U.S.A. in 1914, the practitioners being asked in each case if the diagnosis were certain or uncertain, and the classification was determined by the proportion of uncertain diagnoses in each site. In the accessible group the highest proportion of uncertain diagnoses was 0·6 per cent., while for inaccessible they ranged from 5·3 per cent. to 72 per cent. As the whole point of the division was facility of diagnosis, the method appears to us statistically sound. In any case each site is a separate question, and a true decrease in females of cancer of the uterus cannot be set against an apparent increase in males in some other site. While probably there is no disputing the fact that a large part of the increase in cancer deaths is due partly to change in age composition of the population and partly to better diagnosis, it is questionable whether this accounts for all the increase or only part of it. The effect of age can be estimated statistically by taking rates at ages or by standardisation, but the effect of change of diagnosis can only be tested indirectly and must to some extent be a matter of opinion.

THE DENTISTS REGISTER AND THE NON-PAYMENT OF RETENTION FEES.

THE dental profession has suffered much from the uncertain expression of Acts of Parliament. First of all in 1910 there was trouble over Section 3 of the Dentists Act of 1878, the House of Lords interpreting the words "specially qualified to practise dentistry" in such a way that it was necessary to pass the Act of 1921 in order to overrule the decision in Bellerby *v.* Heyworth. Then in 1924 the case of Binns *v.* The Dental Board showed that the words "served during the late war" in the 1923 Act were capable of a far wider construction than had been supposed. And now it has been necessary to bring a test action in the Court of Chancery to obtain judicial confirmation of the fact that the Acts and Regulations authorise the Dental Board to remove a dentist's name from the register if he has failed to pay his annual retention fee. To uninstructed minds the matter may have appeared simple, but it was stated in court that the Law Officers in England took one view and the Lord Advocate in Scotland took the other; the Dental Board was therefore obliged to go to the law-courts for a definite ruling. The Act of 1921 says that the Board may make regulations about a variety of matters, including "prescribing the fee, not exceeding £5, to be charged in respect of the retention on the register of any person registered after the commencement of this Act in any year subsequent to the year in which that person was first registered." Regulations were accordingly made providing that the annual retention fee should be paid before Dec. 31st, and that in default of payment the registrar should forthwith remove the name from the register. If the Act had merely said that the Board might charge fees and might recover them in the law-courts, it might not have been clear whether the non-payment of a retention fee would justify removal of a name from the register, or would merely give a right of action against the defaulter. But when the Act speaks of a fee "to be charged in respect of the retention on the register of any person registered" it seems obvious to the lay mind that non-payment of fee involves non-retention of name. This is the view which Mr. Justice Astbury took. It had been stated on the other side that the Act of 1878 made a fee payable on registration only and contained no power to remove a name for non-payment of fees. The Acts of 1878 and 1921, it was argued, had to be read together, and there was nothing in the 1921 Act which expressly authorised the strong step of removal from the register —excluding a practitioner from his livelihood—for non-payment of fees. If the authority to remove the name for non-payment were to be found only in the Regulations made under the Acts and not in the Acts themselves, then (the argument continued) the Regulations must be ultra vires. This ingenious argument, however, did not succeed. The Astbury judgment decides that the Regulations are perfectly valid and that the power to charge a fee in respect of the retention of a name on the register means just what the ordinary man would suppose it to mean. It would indeed be surprising if the Dental Board's Regulations were found at fault when the machinery for making them is so elaborate. First the Board makes the Regulations, then it submits them to the General Medical Council for approval. If approved (with or without modifications) they are next submitted for the approval of the Privy Council; indeed they have no effect until the Privy Council agrees to them. Finally the twice approved Regulations are laid before Parliament and during the next 21 days either House may present to His Majesty an address praying for the annulment of any Regulation so laid; if such an address is presented, the Regulation may be annulled by Order in Council and is thenceforth void. It is hard to see what greater check upon the legislation of the Dental Board could be devised.

THE HELMINTHIC PARASITES AND THEIR HOSTS.

IN commemoration of Prof. Bernhard Nocht's seventieth birthday about a hundred students and friends interested in tropical medicine have combined in contributing short articles, on subjects which they have made specially their own, to an imposing and sumptuously illustrated volume [1] comprising over 600 pages and issued by the University of Hamburg. The papers cover a large field, of which one rather neglected corner may be explored—the bearing on practical medicine of the inter-reaction of host and helminthic parasite.

As an index of helminthic infection the general eosinophilic reaction, shown by the percentage of eosinophile leucocytes in the cutaneous circulation, is well known. It is perhaps less appreciated, although the fact was established for hookworm over twenty years ago by Ashford, King, and Igaravidez, that eosinophilia frequently fails in individual cases, often where infections are heaviest. A paper by Hung dealing in mass with persons infected with ankylostomes, ascaris, and trichuris, shows as usual that the average eosinophilia is high. One by Schilling deals with a case in which a dead *Tænia solium* coexisted with an eosinophilia of 50 per cent., and another in which, with a ruptured hydatid cyst, there was no eosinophilia at the critical time, but as the result of the host's reaction to flooding of the peritoneal cavity with the cyst's contents an eosinophilia of 50 per cent. was present three weeks later, when it was of no diagnostic value. Local eosinophilic reaction round a worm is

[1] Hamburgsche Universität. Abhandlungen aus dem Gebiet der Auslandskunde, Band xxvi.; Reihe D, Medizin und Veterinärmedizin, Band ii. Arbeiten über Tropenkrankheiten und deren Grenzgebiete. Bernhard Nocht, zu seinem 70 Geburtstag gewidmet von Freunden und Schülern.

among the subjects dealt with by Hoeppli in a paper which mentions work that he has published elsewhere. Such a reaction may be the only evidence in the tissues that a wandering worm has passed that way; or, with necrosis and fibrosis added, it may serve to illustrate the toxic damage inflicted by parasite on host and the host's efforts to neutralise this damage and imprison the intruder. These local reactions, it is pointed out, are easier to understand than, for example, the apparently complete tolerance by the human body of that energetic wanderer, *Loa loa*. It may be, however, that in onchocerciasis we have a clue to this mystery. In redescribing the histology of the marked giant-celled fibrosis which this nematode produces, Hoeppli's paper will emphasise for the reader the mental association between onchocerciasis and subcutaneous nodules which N. A. Dyce Sharp began to break. The latter has shown that in Nigeria the microfilariæ are found, not essentially in the circulation, but in the lymph from the excoriated back, and that only in 30 to 40 per cent. of persons showing microfilariæ can nodules be detected even with the most thorough examination. Either, then, the species in Nigeria is not *O. volvulus*, although no difference has yet been detected, or nodules are present, but lie deep and impalpable; or onchocerca may, like loa, run free in the body, not always producing an imprisoning reaction. It is perhaps impossible to explain the predominant localisation of microfilariæ in the skin of the back on the supposition of deep nodules, and indeed Dyce Sharp's recent report [2] of the escape of a female *O. volvulus* from the granulating stump of a foot, and apparently not from a nodule, lends force to the last of the three suggestions.

Fülleborn supplies an illuminating note on a deliberate massive infection of his own skin with mature larvæ of *Uncinaria stenocephala* of the dog; an itching, weeping, œdematous area formed from which "creeping eruptions" spread. Complete serial sections of excised skin showed that the tracks were caused by nematode larvæ, corresponding in size to those deliberately introduced, and lying in tunnels filled with fluid and leucocytes burrowed out of the epidermis itself, immediately under the stratum granulosum. Fülleborn is inclined to attribute this position to an oxygen-taxis, but it seems even more likely that only by getting as far away as possible from the healthy lymph of man could this immature parasite of the dog survive in the unnatural host. It seems, too, more reasonable to attribute the marked inflammatory reaction which was present to bacterial infection than to the cervical glands of the larvæ with their estimated weight of 0·000 005 mg. At all events the investigation shows, as did that of Kirby Smith [3] that creeping eruption may be caused by a larval strongyle, so confirming Looss's personal clinical experiences; and in diagnosis this possibility must be added to that of a wandering gnathostoma or gastrophilus. It seems, then, that a creeping eruption is evidence of the restlessness of a parasite in the unnatural and unsuitable medium formed by the epidermis of a non-optimal host, a medium nevertheless not so abhorrent to it as the richly lymph-bathed tissues. It is just this tissue factor which seems to be at the bottom of observations reported by Yokogawa. He finds that the feeding of mature larvæ of the dog hookworm *Ancylostoma caninum* to a non-optimal host, such as the guinea-pig, leads to penetration by the larvæ of the wall of the alimentary canal, and their taking the well-known pulmonary-bronchial-œsophageal route to the stomach, with the added handicap of the liver—compared with larvæ who take the same route after penetrating the skin. If, however, they be fed to the host which they like best, the dog, they mostly develop directly in the intestine without further wandering. From their optimum habitat they make no restless efforts to escape; indeed a larger percentage reaches maturity than is the case after a skin infection. The probable bearing of this observation on human hookworm infection is clea but it remains evident that the opportunity of conta between skin and larvæ in fouled earth is likely to much more frequent than contact between muco and larvæ in fouled water taken to drink. Prophyla will, on the whole, remain unchanged.

PERICARDIAL PAIN.

Dr. J. A. Capps has made an interesting contrib tion [1] to the vexed question of the rôle of pain pericarditis. It has long been recognised th patients suffering from pericarditis often complain pain, and it is equally common knowledge that pe carditis may, on the other hand, be curiously painle throughout its course. Dr. Capps has tried to fi some explanation by which these facts can be cor lated. In four patients with pericardial effusio paracentesis was performed and the inner surfac of the pericardium were explored with a silver wi No pain resulted; nor did scratching of the viscer pericardium produce it. He reports 12 cases, four subacute and chronic pericarditis with large effusion four of simple dry pericarditis, and four of corona thrombosis and dry pericarditis. In the first eig the pericarditis was not associated with pain, and the last four the continuous pain (anginal in typ due to the coronary thrombosis, was not in any w modified by the advent of the pericarditis. From the data he concludes that dry pericarditis is usually painless disease. The explanation of the undoubt pain noted in certain cases of pericarditis is to found in the involvement of the tissues outside t pericardium, more especially the pleura—an extensi of the inflammatory process not uncommon in t pericarditis which complicates rheumatism a pneumonia. Pleuro-pericarditis and antero-posteri mediastinitis are painful, especially a pleuro-pe carditis near the attachment of the pericardium the diaphragm, where the involvement of fibres the phrenic nerve causes pain in the neck. Dr. Cap seems to be justified in his conclusions that t pericardium itself is insensitive and that pericardit per se is painless. The occurrence of pains, of variab site and degree, is due to the involvement of contiguo tissues in the inflammatory process.

[1] Arch. of Intern. Med., 1927, xl., 715.

TUBERCULOSIS IN MONKEYS.

THE serious study of comparative pathology h hardly yet begun, and we are glad to see such goo use made of the opportunities afforded by the Garde of the Zoological Society as is shown in a paper b Dr. H. H. Scott, the Society's pathologist, and Dr. Beattie, lately their anatomist, which is published the current *Journal of Pathology and Bacteriolog* They describe first the anatomy of the lymphat glands and vessels in the thorax and upper abdome of the three anthropoids and a number of old-wor monkeys; the arrangement is essentially the sam in all of them and in man, and new-world monke differ only in having no main thoracic duct. Suc differences as occur are correlated with size, sing glands in small species being replaced by groups glands in larger animals. The details will be examine in the original by those interested; we take note the authors' insistence on the necessity of distinguis ing the mediastinal from the tracheo-bronchial glan which in human pathology are often confused. The then consider rather fully the anatomy of tuberculos in 65 cases in monkeys with special reference to a outbreak of the disease in the monkey house in 192 and compare the lesions with those found in childre in Hong-Kong by Dr. Scott. They find that the monke disease corresponds very closely with the children disease, and recognise the same two broad groups primary infection—respiratory and alimentary; th former is more rapidly fatal, causing death by gener dissemination and sometimes a secondary alimentar

nfection which is promoted perhaps by the fact that nonkeys and apes never spit. What is not repre-ented in the monkeys is the adult type of human uberculosis; there being presumably no tubercle acilli in their natural homes they never receive the mall immunising infections in infancy which so nuch modify the course of human tuberculosis in ater life.

THE VITAMIN ASSAY OF COD-LIVER OIL.

In our last issue (pp. 148–150) appeared a report escribing an extremely interesting attempt to valuate the vitamin A in cod-liver oil. The attempt as made at the instigation of the Second International onference (League of Nations) on the Biological tandardisation of Certain Remedies, and was rganised in this country by the Accessory Food actors Committee of the Medical Research Council nd of the Lister Institute. The object was to ompare the values obtained by a number of different aboratories for the same samples of cod-liver oil ubmitted to all of them. The tests were to be made y the biological method (growth of rats) and one aboratory was to make a colorimetric test, so that s result might be compared with those obtained by he biological method. Apart altogether from its esults the attempt itself marks an epoch, and reveals n a gratifying manner the machinery which we now ossess, whereby the desire of the League of Nations ould be imparted to a number of different labora-ories in this country and their ready coöperation ecured. A few years ago there was no means by hich such a test could be made save by the goodwill f an individual worker in an individual laboratory. ow, besides the machinery already referred to, there lso exists the possibility for a substance to be tested fficially for its vitamin value by submitting it to the itamin-testing department of the British Pharma-eutical Society; indeed, when this department has ad time to get under weigh the claim of any roprietary article to contain vitamins should not be ccepted unless substantiated by such a test. The mpire Marketing Board, too, has a research depart-ent devoted to the study of problems connected with he vitamin values of foodstuffs. Ten years ago the eed for these agencies was already strongly felt, but heir establishment seemed a very remote dream, and here is ground for satisfaction that in that short time hey have come so fully into existence.

As regards the actual results of the tests the findings f the different laboratories are in very tolerable agree-ent where a simple grading of the oils is concerned, ut it is pointed out that in order to assign actual uantitative values to the vitamin A content of the ifferent oils by the biological method, it would be ecessary to use far more experimental animals than as in this case possible, since the variation in the erformance of individual rats is very considerable. he colorimetric method gave results in agreement ith the results of the biological tests, but the report rges that before any conclusion is drawn as to its eneral validity, a comparison should be made of the sults given by it and by the biological method, in ne assay of vitamin A in substances other than od-liver oil, such as butter, palm oil, and cereal oil. he different cod-liver oils used were prepared by ifferent methods and had different histories The sts show that the shorter the history of the oil and ne less its exposure to the air the greater its potency vitamin A, even the factor of the oil being kept in full or a half-filled bottle seemed to make a marked ifference; the liability of vitamin A to destruction y oxidation is, of course, well known.

Following the report appeared a paper (pp. 150–152) y Miss J. L. Leigh Clare and Miss K. M. Soames, who ade the test described above for the Lister Institute, iving further details of their test and the results of heir examination of the same series of oils for itamin D. In testing for this vitamin they find the me wide range of behaviour in individual rats, as in sting for vitamin A, but they were able to grade the oils tested in the same rather rough way as was possible in testing for vitamin A, and to say definitely that whatever the original relationship, there was no fixed quantitative ratio between the amounts of vitamin A and of vitamin D in the oils at the time of testing. They point out that the chief medicinal value of cod-liver oil lies in its content of vitamin D and that to evaluate the vitamin A in a certain oil furnishes no evidence as to its content of vitamin D. They therefore criticise the biological method of testing cod-liver oil, laid down in the United States Pharmacopœia, which aims at the biological assay of vitamin A only.

Everyone who has worked with tests of this type knows how difficult it is to get clean-cut results, unless a vast number of animals is used, and the papers at present under consideration should also be useful in showing what degree of accuracy can be looked for and what degree it is quite useless to expect unless a large series of animals can be used.

THE TAVISTOCK CLINIC.

THE Tavistock Clinic has celebrated its seventh birthday by a general stocktaking, the results of which have just been published. In December, 1919, it was decided to open a psychotherapeutic clinic on an experimental basis of three years, with the understanding that it should be closed if and when hospitals could meet the need. Eight years later despite the establishment of psychotherapeutic clinics at hospitals, there is no talk of closing down, but rather of further expansion. Largely owing to the enthusiasm and wisdom of its honorary director, Dr. H. Crichton Miller, and the devoted services of its first honorary secretary, Mrs. Leith Ross, the Tavistock-square Clinic has come to stay. Since the first patient was received on Sept. 27th, 1920, 2545 cases have passed through it, and it has established a place deep in the hearts of very many of them. Between the Scylla of poverty and the Charybdis of institutionalism, the clinic steers a difficult course. On the latter it has certainly not foundered, for it has a peculiar personal touch which no hospital can well provide. The ideal of the consulting-room has been maintained, although, so greatly has the work outgrown its premises, psychotherapy must now be practised in an area and the children's department works in a basement kitchen. About one-third of the cost of treatment is contributed by the patients, although inability to pay anything is never a reason for refusing admittance. Many of the staff serve on an honorary basis, but workers are still handicapped by the necessity for bazaars, matinées, and other forms of begging inseparable from an inadequate revenue. The history of the furniture in use at the clinic would make a good story; the report asserts that, however it may have been obtained, it was rarely purchased and never stolen. Whether or not the £30,000 they desire would drive them on to Charybdis only the experiment would show; without doubt valuable research material is being wasted for lack of an adequate institute. The children's department deals with every kind of maladjusted child, and an interesting table shows the very high proportion of cases in which neurotic symptoms, other than those complained of, were revealed on investigation. The trained social worker plays an integral part in the treatment of the child patient, for she alone can provide the physician with these data of home and family which are essential pieces in the puzzle. An outstanding feature of work at the clinic has always been the breadth of the survey made of each patient. The case-paper presents the physician with a formidable array of questions covering every system of the patient's economy. The focal sepsis, the endocrine pattern, the stigma of degeneration, the faulty function of any organ or system—all these are taken into consideration before the purely psychogenic factors are allowed to dominate the picture. A laboratory was installed in 1926. A routine physical examination is followed by a labora-

tory overhaul, and, when necessary, by advice from suitable specialists on the honorary consulting staff. Every kind of psychotherapy is in use, but on the whole simple re-education and "autognosis" is most often used. The results are, in general, satisfactory. A questionaire was sent out last year to old patients, inquiring of their welfare. Five hundred replies were received; 44 per cent. recorded "much" benefit from treatment, 32 per cent. "some" benefit, and 22 per cent. little or none. The benefit had been maintained in 61·5 per cent. of the first group, increased in 30 per cent., and 80 per cent. remained fit for work; 17·7 per cent. of those who had received some benefit had improved since treatment. A good reference library for staff and students has now been accumulated. Not least of the activities of the clinic are the lecture courses, both for the public and for medical practitioners. The total attendance during the last seven years is estimated at 27,100, and the lectures are in many cases followed by seminars for more detailed study of the subject. Stress is laid on the practical and prophylactic side of the work. "In the post-war days," says the report, "the audiences were large and fashionable; now they are perhaps smaller, certainly less fashionable, but decidedly more intelligent. Intelligent teachers and thinking parents are recognising more and more that out of the experience of the consulting-room and the clinic there are lessons to be transmitted which have value in the upbringing of the most normal children. . . . Thinking people are recognising that much of our work is devoted to the abnormalities of those who were normal to start with and have been made abnormal by the treatment they have received, generally at the hands of their elders, and often from those who loved them most." We congratulate the Tavistock Clinic on the past and wish it every success in the future.

Dr. Aldo Castellani, Director of Tropical Medicine at the Ross Institute and Hospital for Tropical Diseases, Putney Heath, has been appointed an Honorary Knight Commander of the Order of St. Michael and St. George. Dr. Castellani received from the King of Spain a few weeks ago the Grand Cross of the Order of Civil Merit. He became C.M.G. in 1920, and also holds Italian and Serbian decorations granted in recognition of his outstanding services in the elucidation of tropical disease and as a bacteriologist.

INDEX TO "THE LANCET," VOL. II., 1927.

THE Index and Title-page to Vol. II., 1927, which was completed with the issue of Dec. 31st, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 1, Bedford-street, Strand, W.C. 2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

DONATIONS AND BEQUESTS.—Sir Arthur Everett Shipley, F.R.S., Master of Christ's College, Cambridge, besides other bequests, left £5500 to Christ's College for the endowment of a Fellowship.—During the past month the Royal Manchester Children's Hospital have received over £4000, including a gift of £1000 from Mr. A. W. Cowburn to endow a cot, and legacies of £500 each from Mrs. H. Heynssen and Miss Rosina Lipman.—The Rev. Henry Swann, of West Kensington and Boscombe, Bournemouth, vicar of St. Thomas's, Charterhouse, E.C., who left £113,432, made large charitable gifts, including £1000 to the British Home for Incurables, Streatham, and after other bequests the residue of his property, which amounts to over £20,000, to King Edward's Hospital Fund.—Inspector-General Henry Hadow, who lived at Southsea, left £10,000 stock to Epsom College for the creation of pensions for medical men and their widows, and £100 each to St. Peter's Hospital, Covent-garden, and the Portsmouth and Southern Eye and Ear Hospital, and after other bequests the residue of the property to the Royal Portsmouth Hospital to endow beds to be known as the Ellen Beatrice beds.

Modern Technique in Treatment

A Series of Special Articles, contributed by invitation on the Treatment of Medical and Surgical Conditions

CCLX.—TREATMENT OF MINOR DEGREES OF NASAL OBSTRUCTION.

II.*—NASAL POLYPI AND ETHMOIDAL DISEASE.

NASAL polypi cannot properly be considered except in relation to ethmoidal disease. The day has long passed when a nasal polypus was regarded as a benign new growth. Woakes first pointed out that the polypus was merely a symptom of underlying bony disease, and Lack later set our conception of this abnormality on a sound pathological basis. It is now almost universally conceded that the presence of nasal polypi and of ethmoidal inflammatory changes are intimately associated, a presumption which is strengthened by the fact that the more thoroughly the bone at the base of a polypus is removed, the less is the likelihood of the polypus recurring. It is then of the utmost importance that the practitioner should have some criterion as to the amount of associated bony disease present, and it may be taken that clinically the number and nature of the polypi give a valuable indication. The presence of merely one or two pedunculated polypi shows that the osteitis is localised or even arrested; but where numerous small polypi occur, especially if associated with unhealthy mucous membrane in the vicinity the bony affection is probably widespread and active. Thus by visual inspection of the nasal cavities the practitioner may glean much useful information as to the prognosis and the extent of the necessary operative treatment. A good skiagram is of the utmost value in determining the presence of an associated accessory sinus infection or the extent of the ethmoidal disease. In the case of a choanal polyp, the skiagram may show some involvement of the maxillary antrum, although paradoxically enough the antrum may on transillumination appear to be brighter on the affected side.

Incidence and Symptoms.

Polypi are most often met with during the third and fourth decades, and are stated to be very rare under the age of 10 years; but during the past year I have seen three cases in girls of 8 years and under, in which the polypi were removed with the snare, and shown by histological examination to be of the ordinary character. They vary greatly in size and number, but usually appear as greyish, gelatinous oyster-like masses, especially when they are of the pedunculated variety. If, however, they protrude into the vestibule, or into the naso-pharynx, they may be reddish in colour and simulate a papilloma. Almost invariably they originate from the ethmoidal region under cover of the middle turbinal, and this is an important factor in the correct diagnosis. The other point to be borne constantly in mind is that they are freely movable with a probe, and examination with the probe should therefore be the invariable rule. Observance of the above two points should prevent mistakes in connexion with hyperplastic growths; these are not thus freely movable and often spring from the inferior meatal region. Other conditions are less likely to be mistaken for polypi, but it must not be forgotten that a malignant growth of the ethmoid may be overlaid by polypi, so that the real condition only becomes evident after the latter have been removed. Frequent attacks of spontaneous epistaxis in the presence of polypi should arouse suspicion of malignant disease. The use of cocain plus the probe will serve to distinguish between true polypi and mere turgescence of the turbinals. The main symptoms are those of nasal obstruction, and patients often complain that such obstruction varies with the state of the barometer, being aggravated by cold or damp weather. Occasionally the sufferer states that he has something which flaps like a valve

* Part I., on Deflections of the Septum and Abnormalities of Turbinate Bones, appeared last week.

n the nose, or, as mentioned above, the polyp may ven present at the anterior naris. The obstruction is requently associated with a profuse nasal discharge f varying consistency. There is often a peculiar asal intonation of the voice, and in severe cases the asal bridge may be obviously distended. Aprosexia nd anosmia are not infrequent, whilst supra- or nfra-orbital neuralgia may be complained of. Hay ever and asthma are often aggravated, if not caused, y the presence of polypi, whilst a dry purposeless ough is frequently a part of the train of symptoms. A certain degree of deafness or giddiness is at times roduced, and some authorities state that polypi may e a cause of epilepsy.

Prognosis.

Prognosis is extremely difficult. If polypi are eft untreated, they tend to increase in size and umber, and may in time lead to marked impairment f the general health or even to serious complications. t is obvious that some form of operative interference s necessary, and that topical applications can have o curative effect where bony changes are present. A few prognostic points may however be formulated.

1. A single pedunculated polypus—especially if cystic n nature—does not tend to recur after local removal.

2. Polypi associated with obvious disease of an accessory inus are amenable to treatment if the patient is prepared to ace the appropriate operation.

3. Even though the patient refuse a radical operation e may be promised considerable relief of the obstructive ymptoms if he will permit of occasional removal of the olypi by means of the snare.

4. In the case of the choanal polypus, its removal is sually curative in effect, as the bony disease has almost nvariably been arrested by the time the polypus is discovered.

Treatment.

The treatment may be: (1) simple removal of the olypi by the snare; or (2) radical removal of the olypi and the underlying diseased bone.

In *simple removal* it is necessary to have: (*a*) good næsthesia; (*b*) good illumination; and (*c*) a good nare. Local anæsthesia suffices, and may be induced y the application of cotton-wool pledgets soaked in 0 per cent. cocaine solution (and well squeezed out) o the polypi and their attachments. Efficient lumination is an obvious necessity where the work as to be done in a confined space such as the nasal avity. The best snare is Glegg's, which has the dvantages mentioned in the previous article, and in hich the end of the barrel is crossed by a bar. This revents the wire from being drawn into the barrel, nd the polypus is thus torn away from its attachments nd not merely cut through at the level of the wire s by a sharp guillotine.

The wire noose is gently slipped round the lower end of he polypus and then with a slight side-to-side movement s insinuated under cover of the middle turbinal to reach he attachment of the growth. The noose is then tightened, nd the polypus sharply pulled away from its attachment. s a rule, the whole of the pedicle will come away, often ccompanied by a scale of the subjacent bone. In some ases when the polypi are growing from the anterior end f the middle turbinal, the latter may be removed with the olypi; such removal is beneficial as it diminishes the kelihood of recurrence. Should bleeding obscure the iew, it is well to press on the area with a mop of cotton-wool oaked in hydrogen peroxide, which for this purpose is a etter and safer styptic than adrenalin. If both sides of the ose are affected, we should endeavour to clear one side ompletely in order to restore nasal respiration, and defer reatment of the second side for a week or ten days. Rather risk hæmorrhage may follow, but can usually be controlled y applying compresses of iced water to the bridge of the ose; if it persist a little cotton-wool, soaked in hydrogen eroxide, may be temporarily packed into the nose. This hould be removed in ten minutes, when a loose pledget of ry wool may be inserted in the vestibule to prevent blood rickling over the lip. In no circumstances should the ose be tightly packed with gauze, lest severe sepsis super- ene. The immediate after-treatment consists in trickling few drops of hydrogen peroxide into the nostril at frequent ntervals for two to three days; later a mild nasal wash should e used several times daily for a week. Another important art of the after-treatment is the regular inspection of the ose for recurrence of growth and the immediate removal hereof. Recurrences should be dealt with promptly.

With patience and perseverence even bad cases of polypi can thus be cured, but if after several careful removals the condition persists, a more radical procedure must be adopted.

For the more *radical operations* the question of anæsthesia must first be considered. Local anæsthesia by cocainisation (with or without adrenalin) may suffice, especially if induced by Sluder's method, where a pledget of wool dipped in a saturated solution of cocaine is pushed up under the posterior end of the middle turbinal whilst a similar one is pushed up into the antero-superior part of the nose, both being left in situ for ten minutes. In this way the branches from the spheno-palatine ganglion and the nasal branches of the ophthalmic division are dealt with, and excellent anæsthesia results. In many cases, however, it is preferable to induce general anæsthesia after packing the nasal cavities with wool soaked in 10 per cent. cocaine. If general anæsthesia be employed, it is important to remember that the use of adrenalin to stop hæmorrhage during the operation may be fraught with danger. As far as possible the polypi are first removed with a snare or Luc's forceps, and the subjacent diseased bone is then cut away by Luc's or Grunwald's forceps, or by Meyer's ring knife. It is of the utmost importance to avoid injury to the cribriform plate, and these manipulations should therefore be performed below the level of attachment of the middle turbinal, and the ring knife must be drawn from behind forwards and slightly downwards. Any attempt to cauterise the base of the polypus is at once useless and dangerous.

The after-treatment is as before—instillation of hydrogen peroxide drops will almost invariably arrest the hæmorrhage, and no attempt to pack the nose tightly is justifiable, save as a last resort.

Naturally, if associated accessory sinus disease be present, it must be dealt with by suitable operation. Kisch has lately reported an external operation for the treatment of ethmoidal affections, but at present its execution should be confined to those who are accustomed to perform extensive intranasal operations.

Difficulties which may Confront the Operator.

In a small percentage of cases the removal of polypi seems to cause a violent reaction in the ethmoidal region, and when next seen the patient has produced a copious crop of œdematous polypi. In such, it is well to hold one's hand and wait for the congestion to subside ere removing these fresh polypi. If this be done, a much longer period of immunity from recurrence will follow the second operation. In the treatment of the choanal polypus, a general anæsthetic is desirable, when a finger may be passed into the naso-pharynx to facilitate adjustment of the loop of the snare. Here, again, Glegg's snare will be found most convenient, for a large loop may first be passed over the polypus and then easily adjusted so that it will grip the pedicle firmly. In some cases it may be found necessary to introduce a pair of curved forceps into the naso-pharynx, grasp the pedicle therewith, and tear it from its attachment.

The major difficulties encountered, however, are due to spurs and deviations of the septum. Such obstructions may not be recognised until the anterior polypi have been removed, and it is in these circumstances that efficient illumination and cocainisation are of the utmost value. If the hæmorrhage be profuse and obscure the view, it is better to have the strength of mind to desist for the time being, and to postpone the completion of the operation for 10 to 14 days. Manipulation in the dark will lead only to incomplete removal of the polypi and the causation of troublesome adhesions. In cases of marked septal deflection it may be necessary, or at least advisable, to perform a submucous resection before dealing with the polypi.

Finally, it should be borne in mind that children tolerate cocaine badly, and strong solutions therefore should on no account be used for them.

MILK CONSUMPTION AND THE GROWTH OF SCHOOL-CHILDREN.

Preliminary Report on Tests to the Scottish Board of Health,

BY J. B. ORR, *D.S.O., M.C.*, M.D., D.SC. GLASG.,
CHAIRMAN OF RESEARCH COMMITTEE OF SCOTTISH MILK AND HEALTH ASSOCIATION.

DURING the past few years a number of tests have been carried out in America [1 2 3] to determine the nutritive value of milk for children. More recently a test under exact conditions in a labour colony for boys, where the whole diet was controlled, was carried out by Dr. Corry Mann [4] for the Medical Research Council. The results of all these tests which are in general agreement have demonstrated the high nutritive value of milk for growth.

In 1926–27 a large-scale test was carried out in schools in seven cities and towns in Scotland and in Belfast to determine whether the results obtained by Corry Mann under the rather special conditions of an institutional school would be obtained in children attending elementary schools and receiving the varied and changing diet of the ordinary working-class household.

The tests were conducted under the auspices of a committee appointed by the Board of Health for Scotland with Sir Leslie Mackenzie as chairman. The committee consisted of the school medical officers for the cities and towns where the work was carried out. The collection of data was undertaken by four women medical officers. The clinical examination of the children was made by the late Dr. L. D. Cruickshank, of the Scottish Board of Health, and the school medical officers.

A repeat test is at present being undertaken under the supervision of Dr. Gerald Leighton, Scottish Board of Health, and a full report will be issued when the new test is completed.

The results obtained to date, however, so strongly confirm those of Corry Mann and previous workers which are of such importance in public health that it has been thought advisable to issue the present interim report.

Method.

At each centre four groups of children were taken, each from 40 to 50, according to the size of the classes in the school. One group received whole milk, a second separated milk, and a third a biscuit of the same energy-yielding value as the separated milk. The fourth group, which acted as control, received no supplementary feeding. The test began at the end of November and finished at the end of June. The Belfast test did not begin till the end of January; it is, therefore, not included in the results of the seven month experiment.

At Peterhead and Greenock the children were between 5 and 6 years of age, at Dundee and Edinburgh between 8 and 9 years, and at Aberdeen and Paisley between 13 and 14 years. Glasgow and Belfast had a series of groups of each of the three ages. There were thus under test children at the beginning, the middle, and the end of school life. The 5- to 6-year-old children received three-quarters of a pint of milk per school day, the 8 to 9 one pint, and the 13 to 14 one and a quarter pints. The milk was given at school.

Owing to unforeseen difficulties the tests in Glasgow had to be rearranged about three months after they had been begun, and the whole-milk group was dropped. The Glasgow data, therefore, are limited to the control, biscuit, and separated milk groups.

Weights and Heights.

It was intended to weigh the children with only one layer of underclothing. This was found to be impracticable. The children were therefore weighe in indoor clothing, without shoes, and there a considerable fluctuations in the weight figures, ev those taken on successive days. The average weig of clothing was ascertained month by month and t necessary addition or deduction made in the fin weight figure. Owing to these circumstances t records of individual weights are not so reliable indication of the influence of milk as the figur showing the increase in height.

The weights were recorded to the nearest quart pound. The heights were recorded to the neare quarter inch, the children being measured witho shoes. The measurements were taken on thr consecutive days at the beginning and end of t test and at intervals of about one month during i progress.

Before the results were calculated such cards we rejected as showed absence due to serious illnes about 25 per cent. of missed feeds, doubtful increas in weight or height, &c. This accounts for t decreased number of children available for the fin analysis.

The *average* increase in height and weight has be worked out per group at each age and in each centr giving the results shown in Table I.

The height increases when all the groups at o age, irrespective of locality, are combined, show ve strikingly the influence of the milk supplement aiding growth, and the failure of the biscuit supp ment. Table III. gives the mean increase (in inch in each group at each age, with the probable erro

At every age the increase in height of the who milk or the separated-milk groups is significant greater than that of the biscuit or control grou while the difference in increase in height between t two milk groups is insignificant. The supplementa biscuit, on the other hand, fails to exercise a significant stimulus in the 8-year-old group, a in the 13- and 5-year-old groups has an almo significantly retarding effect.

As the milk groups (whether separated or who showed a distinct improvement in growth over t non-milk—i.e., biscuit and control—groups, t figures of the *average* increase at all ages were arrang into two groups, with the results shown in Table I

This seven months' experiment thus shows average monthly increase of 0·17 in. and 0·42 lb. the non-milk groups, and of 0·21 in. and 0·52 lb. the milk groups. In the much lengthier experime by Corry Mann the corresponding figures we 0·15 in. and 0·32 lb. for all boys on the basal di and 0·22 in. and 0·58 lb. for all boys receiving t supplement of one pint of pasteurised milk eve day, the milk group increases in height in bo

xperiments, thus approximating very closely in ›ite of the Scotch children receiving the supplement nly five days per week.

The children in the different groups at the various entres were examined at the end of the experiment nd clinical observations made. Independent reports ere also handed in by the headmasters of the schools. hese clinical reports, which cannot be expressed in gures, show that at most of the centres the children ho had received milk appeared to be in better ondition than those receiving no milk. It was oted that, on the whole, they had glossier hair and

learer complexions and held themselves more erect. t other centres this difference was less marked, and n Glasgow no distinct difference could be detected. he most marked improvement in the children in ne milk groups was shown in children who had been n poor condition at the beginning of the test.

From the particulars gathered as to the home ietary of 626 households it would seem that the verage milk consumption in the home was 2·5 pints er head per week. The total milk consumption of ne children under test in these homes was then alculated on the assumption that the average con- umption per head in the household to which the

hild belonged was the home consumption of that hild, to which was added the amount received at chool. The rate of growth of children receiving nore than the average of the total milk consumption (home plus school) was compared with that of children receiving less than the average. Table V. shows the average rate of increase in height, in the " over average " and " under average " milk consumption groups.

Conclusions.

From this survey of the data it seems probable that, in the final report, it will be possible to draw the following conclusions :—

1. The addition of the milk to the diet of school-children, during the seven months' experimental period, has been accompanied by a rate of growth as indicated by an increase in both height and weight 20 per cent. greater than that in children not receiving the extra milk.

2. This increase in rate of growth has been accompanied by an improvement in the general condition of many of the children receiving milk.

3. Separated milk is of great value for promoting growth. Its nutritive value for children would appear to be under-estimated.

The writer wishes to record his indebtedness to Miss M. L. Clark, who has prepared the above tables, for valuable services in connexion with the supervision of the tests during their progress. Dr. Lewis D. Cruickshank, who superintended the investigation from the administrative side on behalf of the Committee, died towards the end of the test period, and we can only record our profound regret that we have not had the continued advantage of his intimate knowledge of school and social conditions.

The cost of the above tests was defrayed by a grant made by the Empire Marketing Board to the Rowett Research Institute, Aberdeen.

SHEFFIELD HOSPITAL SUNDAY FUND.—This fund will keep its " diamond jubilee " this year, having been established in 1868. It is hoped to raise £6000, being £100 for each of the 60 years. Last year the amount was £3648, the successful penny-in-the-pound scheme having retarded the progress of the fund. The number of patients treated in the Sheffield hospitals last year equalled about one-quarter of the population of the city—there were more than 14,000 in-patients and more than 111,000 out-patients.

THE APPARENT INCREASE OF CANCER.

By D. F. SHEARER, M.B. Oxf., F.R.C.S. Eng.

Some years ago Dr. Stevenson published (in the annual report of the Registrar-General for 1917) an exhaustive analysis of the records of the deaths from cancer in order to determine how far the apparent increase of cancer was actual and to what extent it was the result of improved methods of diagnosis and certification, and concluded that these improvements were not sufficient to account for the increase. The present investigation was made to learn whether the conclusions then arrived at were confirmed by the figures of more recent years but the method adopted differs from that of Dr. Stevenson in three important particulars. For the most part the conclusions of Dr. Stevenson were based on crude death-rates. Here only standardised figures are used; and the error that may arise from the use of crude rates is well shown in the case of the tongue in the male. Using crude rates cancer of the tongue rose between 1913 and 1925 from 56 to 63 per million living; standardisation shows that in fact cancer of the tongue had fallen from 70 to 63 per million living. In the second place Dr. Stevenson grouped the sites of cancer into accessible and inaccessible, a distinction which is one of opinion and not of statistical fact. Here the grouping is made by rate of increase or decrease, and the resulting composition of the groups speaks for itself in relation to improvement in diagnosis and certification. Thirdly, the question is investigated of what change has taken place in regard to the large group of ill-defined deaths in later years of life which are attributed to "old age."

Table I. shows the actual numbers of deaths in both sexes, at all sites and in all age-groups of 1925 and 1913; and the standardised figures for 1913 based on the change in population at each age-group.

TABLE I.—*Showing the Numbers of Deaths in 1925 and in 1913 and the Numbers in 1913 standardised for Change of Population at 12 Age-groups, at All Sites in each Sex, and for the Tongue and Jaw in the Male Sex.*

Standardised figures for 1913 exceeding the corresponding figures for 1925 shown in italics.

The number of deaths in 1925 was 51,939, while the actual and standardised figures for 1913 were 39,13 and 49,979 respectively. The increase of 12,800 is therefore reduced to 1960; made up of an increase in the male sex of 2258 and a decrease in the female of 298. Dividing into two main age-groups, under and over 65, it appears that at the lower age there is an increase in the males of only 96 and a decrease in the females of 1350; while in the later years the males increase by 2162 and the females by 1052.

It has not been found possible to print the full table showing the actual and standardised figures for each site. The male tongue and jaw are, however, given to show how the results are arrived at and these sites have been selected in view of Dr. Stevenson's statement in 1917. "The jaw and tongue furnish

instances the significance of which can hardly be called in question."

The proportion which the deaths at each site in 1925 bore to the deaths at the same site in 1913 (standardised) was then calculated and fell into three natural groups in the male. Similar groups were formed for the females together with a fourth which contained all sex organs. Table II. shows the result, and Table III. gives the constituents of each group. Group A is clearly composed of sites at which the diagnosis of cancer can be made by any practitioner; Group C is equally clearly composed of sites at which the diagnosis of cancer can only be made and is only made by practitioners who have devoted special attention to diseases of these sites. Group B includes cases of both varieties. It is interesting to note that Group D corresponds almost exactly with the figures for all sites in the same sex.

TABLE IV.—*Showing the Number of Deaths from Cancer in 1925 and 1913 (Standardised) Under and Over 65 and the Increases and Decreases; together with the Decreases in "Old Age."*

—	Males.		Females.	
	Under 65.	Over 65.	Under 65.	Over 65.
1925	12,847	11,155	15,562	12,375
1913	12,751	8,993	16,912	11,323
Increase or decrease	+96	+2,162	−1,350	+1,052
"Old age" decrease	..	−6,989	..	−5,510

Taken in conjunction with Table V. it is evident that Group C is the chief factor in producing the increase at lower years in the male; and it will be noticed that in each of the three ten-year age-groups up to 65 Group C is responsible for all the increase. And whatever opinion may be held as to the propriety of taking Group C as evidence of improvement in diagnosis the statistical fact is indisputable that out of an aggregate increase in both sexes of 1960 Group C is responsible for 1722.

During the period under investigation there has been a decrease after standardisation in the number of deaths attributed to "old age" of no less than 12,499; in the males of 6989 and in the females of 5510. Table VI. shows the percentages of deaths from cancer, old age, and other causes at the various age-groups in both years, from which it is clear that if the decrease in "old age" is distributed between cancer and other causes in due proportion the bulk if not the whole of the increase in cancer is accounted for. There is, however, one point at which the three factors, increase of population, improvement in diagnosis in Group C, and decrease of "old age," seem to be insufficient to account for the rise; that is between the ages of 65 and 70 in the male. The standardised increase at this age-group is 640, of which 227 are contributed by Group C. The decrease in "old age" is, however, only 447, and unless we were to assume that all these were cancer cases some further explanation is required. For some reason the rate of increase at this age is greater than in either the preceding or the succeeding five-year group, and inspection of the rates of increase at sites shows that it is attributable to an abnormal rise at two sites—stomach and intestine. It may be worth noting that at this age-group the fall in the death-rate due to causes other than cancer is less than in either of the adjacent age-groups.

TABLE VI.—*Giving the Deaths from Cancer, "Old Age," and other Causes Out of the Total Deaths at Age-groups Over 55 in 1925 and 1913.*

Ages	55–60	60–65	65–70	70–75	75–80	80–
Males.						
1925.						
Cancer	19·3	19·8	17·4	15	11	6
Old age	—	—	1·4	6·8	13	25·7
Other causes ..	80·6	80·2	81·2	78·1	76	68·3
1913.						
Cancer	15	15·4	14·1	10·3	8·3	4·5
Old age	—	—	3·2	12·7	21·4	45·1
Other causes ..	85	84·6	82·7	77	70·3	50·4
Females.						
1925.						
Cancer	24	22·6	19·1	14·7	11	6·4
Old age	—	—	2	7·6	13·8	28·2
Other causes ..	76	77·4	78·9	78·7	75·2	65·4
1913.						
Cancer	21·4	19·8	17·1	12·6	9·4	5
Old age	—	—	3·7	13·1	22·1	40·8
Other causes ..	78·6	80·2	79·2	74·3	68·5	54·2

Generally speaking, the statistics here brought forward tend to show that the increase of deaths from cancer is merely an apparent increase, and that there is in fact some slight decrease after due allowance is made for change of age-distribution of the population and for improvements in diagnosis and certification.

MEDICINE AND THE LAW.

A Gap in the Factory Acts.

WHILE the general revision of the Factory and Workshop Act seems for the moment to be as far off as ever, a specific omission in the existing law was disclosed at a recent inquest at Norwich. A fire occurred at a match store at Timberhill, Norwich, on Jan. 8th, and three women lost their lives. Dr. R. J. Mills (who had conducted the post-mortem examination) in his evidence before the coroner said that death was due to carbon monoxide poisoning, and must have happened before the burning, though the bodies were badly burned afterwards. One-fifth of the matches in the store caught fire, but this fraction was enough to cause immediate death. The coroner stated that he had taken the opinion of the Home Office upon the question whether the premises were to be deemed a factory within the Factory and Workshop Act or not. The answer was that the premises were not within the statutory provisions as to safety from fire. Nor, it appears, are matches to be deemed explosives within the Explosives Act. It is not surprising that the coroner's jury, when returning a verdict of "accidental death," added a rider unanimously recommending that goods of so dangerous a nature as matches should be stored under conditions which would better protect the workers' safety.

Penalties for Sale of Diseased Meat.

Public opinion will support the infliction of heavy sentences upon persons found guilty of the dangerous and disgusting practice of selling diseased meat for human food. In two prosecutions for this offence, recently recorded in the *Times*, the magistrates evidently took a serious view. Rose Hannah Gill, a butcher carrying on business in Bridgeman-street, Bolton, was fined various amounts totalling £180; inspectors gave evidence that they found 400 lb. of tuberculous meat on her premises in a cellar beneath the living-room, it being necessary to move furniture from the trap door giving access to the cellar. In another case, dealt with at the Marylebone police-court by Mr. Bingley, the stipendiary magistrate, a fine of £25 was imposed upon Eastmans, Ltd., of West Smithfield. In this case a joint of diseased meat attracted an inspector's attention. The defence was that it was part of a sheep's carcass from Australia and that it was most unlikely that the meat would be diseased. In passing sentence, Mr. Bingley criticised the inspector's failure to take immediate steps to discover what had happened to the rest of the carcass. The magistrate had little doubt that the other parts of the sheep had been sold to unsuspecting purchasers for human consumption. He commented on the fact that the maximum sentence (presumably under Section 47 of the Public Health (London) Act of 1891) was a fine of £50 or six months' imprisonment with or without hard labour, and he added that,

even if he wished to do so, he could not send a limited company to prison.

Charge of Cruelty to Animals: Successful Appeal.

If cats have to be destroyed, what is the most satisfactory method? Mr. R. J. Sargent, veterinary inspector to the Guildford Corporation, was fined £10 with £10 10*s*. costs last November for causing unnecessary suffering to two cats. It was stated at the police-court that he placed the cats in a lethal chamber containing chloroform for half an hour with a closed vent-hole, that when he took the cats afterwards to the destructor works they were still breathing, and that he then hit them with a sledge-hammer. A veterinary surgeon, giving evidence for the prosecution (conducted by the R.S.P.C.A.) said that he himself formerly kept the vent-hole of the lethal chamber closed when destroying cats, but that, having come to the conclusion that his former practice was cruel, he now kept the vent-hole open till the cats became unconscious. A cat, he said, should be kept in the chamber for at least an hour, and these two cats, if still alive, should have been killed by drowning, not by blows from a hammer. The defendant, who said he had destroyed about 600 cats in two years for a Guildford society, gave evidence that in his experience half an hour in the lethal chamber was sufficient. He was supported by Prof. Hobday, principal of the Royal Veterinary College, and other witnesses, and his appeal (to the Guildford Quarter Sessions) was allowed with costs.

IRELAND.

(FROM OUR OWN CORRESPONDENTS.)

The Cancer Campaign in Ireland.

A MEETING to further the Cancer Campaign in Ireland was held at Belfast on Jan. 5th, being summoned by the Ulster Medical Society and the Ulster Branch of the British Medical Association. Dr. J. C. Rankin, President of the Ulster Medical Society, presided, and Mr. S. S. Pringle, of Dublin, outlined the objects of the Cancer Campaign in Ireland and the progress already attained. Among those who took part in the subsequent discussion were Dr. William Porter, Mr. Andrew Fullerton, the Marquis of Dufferin and Ava, Dr. Livingstone, Vice-Chancellor of the Queen's University of Belfast, Prof. R. J. Johnstone, M.P., Mr. Bryan Moore, Prof. J. A. Lindsay, Mr. A. B. Mitchell, and Dr. Leonard Kidd. The following resolutions were passed unanimously:—

1. That the National Cancer Campaign is worthy of support and that a Northern Ireland branch be established for the purpose of informing the public as to what is already known about cancer and of raising funds to assist in further investigation of the problems still unsolved.

2. That this meeting is of opinion that the plan of the National Cancer Campaign is the most suitable that can be adopted and is the most likely to lead to further progress, as under the present scheme those hospitals and laboratories which are already engaged in the treatment and investigation of cases of cancer will be assisted and encouraged to pursue their activities under a central direction, so that full use will be made of the services of their staffs of trained research workers, and of surgical, radiological, and biochemical experts.

3. That this meeting agrees with the decision of the National Cancer Campaign that it is not expedient to establish new special hospitals for the treatment and investigation of cancer, and that the results hoped for are more likely to be attained by development of the institutions already established.

A committee was appointed to carry out the objects of the meeting.

Maternity Accommodation in Belfast.

It has been recognised for some time that the existing accommodation for maternity work in Belfast is wholly inadequate. The present maternity hospital, which was opened in 1903, is a small institution and the pressure upon its accommodation has been constantly increasing. The need for better facilities has become urgent. There are reasons why the extension of the hospital on the present site would be difficult, and as an alternative it has been proposed that the Maternity Hospital should amalgamate with the Royal Victoria Hospital, which would erect a maternity block. This suggestion has been under consideration for several months, and has now been unanimously approved by the Corporation of the Royal Victoria Hospital and the Incorporated Society of the Maternity Hospital. It has been pointed out that this policy has many advantages. It is in line with the growing recognition of the desirability of all general voluntary hospitals including maternity work in their operations, as is the general practice in the United States and in Canada. Such association tends to efficiency and to economy. Maternity hospitals can hardly afford the expensive special departments which are now provided by all the great general hospitals, and collaboration of the staffs of the different departments is obviously highly desirable. The training of students and of nurses is facilitated by such an arrangement. Belfast has a large and flourishing medical school, but at present, owing to the lack of maternity accommodation in the city, many students have to seek their maternity training elsewhere. Economy is likewise secured by a joint administration, for small hospitals are necessarily more expensive to run than large hospitals. The present cost per bed per annum in the Royal Victoria Hospital is approximately £130, whereas the cost in the maternity hospital is approximately £170.

It is well known that the mortality in childbirth in the kingdom has been but little reduced in recent years and remains round about 4 deaths in 1000 deliveries. No one doubts that this mortality is largely preventable, or that its principal cause is the lack of adequate institutional treatment for maternity cases. The mortality in a well-equipped maternity hospital is very low, and in some cases almost negligible.

Steps have already been taken to effect the amalgamation of the maternity hospital with the Royal Victoria Hospital as promptly as possible. An appeal for £100,000 is being prepared, and the Duchess of Abercorn has consented to head the movement. The proposal is to erect a maternity block of 100 beds with facilities for extension.

Lunacy in the Irish Free State.

The report of the Inspector of Mental Hospitals in the Irish Free State for 1926 has recently been issued. The number of insane persons under care at the end of the year was 19,887, of whom 10,369 were males and 9518 females. There was an increase of 348 during the year, but the number was less by 249 than at the end of 1915. The number of deaths was 1037 and of discharges 1347, of whom 1051 were discharged as recovered. There were five deaths by suicide. The average cost per patient in the public mental hospitals was £49 1*s*. 4*d*. There are still 1994 insane patients in poor-law institutions.

The committee of the Grangegorman Mental Hospital—the asylum for the counties of Dublin and Louth—is occupied with the problem of providing additional accommodation. There are 200 more patients than in 1923, and the population of the asylum has virtually doubled in 30 years. It is stated that the Government will not allow any scheme of additional building to be undertaken until there has been time for consideration of the report of the Poor-Law Commission.

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

Sale of Carbolic Acid.

THE Board of Health announces that in future no carbolic acid may be retailed to any person except on a medical man's prescription. An exception is made for solutions of less than 5 per cent. The Board's action can hardly be called timely, for it should have been taken years ago when the news

apers first pointed out how easy it was for would-be uicides to obtain the poison. Carbolic acid causes a eath which is painful beyond ready description, but he victim usually finds this out too late. It is one f the cheapest and most readily available means of elf-destruction and in this country is used in nearly ne-third of all suicides being especially attractive to omen. There is reason to believe that the new law ill do more than drive the desperate to other means f self-destruction.

Action of Salicylates on the Kidneys.

Dr. Dumitriu Popesco has carefully examined the rine of a number of patients who were receiving alicylates for rheumatism and had not previously uffered from disease of the kidneys. His investigaions make it clear, he says, that renal irritation may ollow the use of these drugs, but he does not regard his as an important argument against their use as he damage is not serious. Dr. Avramescu, studying he same subject, has made somewhat different bservations. Whilst pointing out that albumin and asts are found in large numbers of normal individuals, nd are therefore present in many rheumatic patients efore treatment begins, he states that when salicylates re exhibited the casts become more numerous, pithelial cells are abundant, and a desquamative atarrh of the entire urogenital tract is sometimes set p. He has even found coarse granular and waxy asts in some cases. An unusual feature of this form f renal inflammation is that it disappears even if dministration of salicylates in large doses is continued. linical symptoms of nephritis never appear, and it eems that if the patient is already suffering from this isease in a chronic form the antirheumatic drugs will uickly cause a fall in the quantity of albumin xcreted. The above observations, therefore, appear o have a theoretical rather than a practical value.

Total Extirpation of the Larynx for Carcinoma.

Dr. Paul Steiner has recently reported the following ase to the Cluj Medical Society :—

An agricultural labourer, aged 55, had been hoarse for ome months and had lost 21 lb. in weight. Examination ith the laryngoscope showed a new growth on the right ocal cord, which in some places had become cicatrised and odular. At a subsequent examination Dr. Steiner excised small piece of the growth intralaryngeally, and under the icroscope it was found to be carcinomatous. No infiltrated lands were present in the neck and the larynx was removed n Nov. 30th, 1927, under deep narcosis without previous racheotomy, a cannula being used only after the operation as over. As soon as the wound had healed an artificial arynx, as modified by Bruns, was brought into use, and this s still worn by the patient, who speaks quite intelligibly nd can make himself heard in a large room.

It was found that the growth occupied the whole left alf of the larynx, extending over the midline in front, nd downwards as far as the cricoid cartilage. Judging rom these appearances the patient could be cured nly by total excision of his larynx, and as Dr. Steiner oints out, his experience justifies the statement that reliminary tracheotomy is not always required in perations of this kind.

The Care of Old Age.

In the course of a popular lecture delivered here ome time ago Dr. Burghardt dealt with the means hat may be taken to preserve activity of mind and ody in the aged. It is universally admitted, he said, hat after middle life the amount of food taken should iminish, and the aim should be to decrease the onsumption of the structure-forming materials of iet, though they should not be dispensed with ntirely. Relatively little should be taken of the timulating elements of food which are used to make t attractive, and, in brief, we should eat no more han the perfectly normal appetite craves for, and s little as possible of those things which are merely greeable. As the period of old age approaches the egimen should be definitely simplified and meals hould always be taken with deliberation. Bread, milk, nd fruit are the most beneficial foods at this period of life. The tendency of old people to stay indoors should be discouraged, and too much heavy clothing should not be worn. The idea that the old should live as much like vegetables as possible, taking no exercise whatever, is erroneous and makes for premature decay. The disinclination to move and make efforts may be rather the result of under-oxygenation, of habit, or of what may almost be called senile laziness, than of an instinctive impulse towards functional economy. The real remedy for stiffness, digestive troubles, and the other discomforts and disturbances of old age is healthy exercise and a suitable diet.

The Services.

COMMISSIONS IN THE INDIAN MEDICAL SERVICE.

A CERTAIN number of appointments will shortly be made for permanent commissions. Well-qualified men of European descent, under 32 years of age, who wish to enter the Service should apply to the Under Secretary of State for India, Military Department, India Office, London, S.W. 1. The selected candidates will be required to attend a course of instruction in this country, commencing not later than Feb. 16th, prior to sailing for India in the early autumn. An announcement appears in our advertisement columns.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. F. E. Anley is placed on the Retd. List with the rank of Surg. Capt.

Surg. Comdr. A. G. Malcolm to *President* for course at R.A.F. Medical Officers' School of Instruction.

Surg. Lt.-Comdr. A. H. Harkins to *Delhi.*

Surg. Lt. F. W. Besley to *Broke.*

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. C. R. Sylvester-Bradley, half-pay list, late R.A.M.C., retires on ret. pay on account of ill-health.

Capt. B. L. Davis to be Maj. (Prov.).

TERRITORIAL ARMY.

Capt. G. L. Pillans, late R.A.M.C., to be Lt., and reinquishes the rank of Capt.

INDIAN MEDICAL SERVICE.

The undermentioned officers relinquish their temp. commns. : Temp. Capts. Abinash Krishna Sen and Krishna Das Mukharji (and retain their rank), and Temp. Lt. Venkatachari Srinivasan.

ROYAL AIR FORCE.

Flying Officer J. D'Isney Rear is promoted to the rank of Flight Lt.

DEATHS IN THE SERVICES.

Lieut.-Colonel Robert Tilbury Brown, C.M.G., late R.A.M.C., who died on Jan. 21st, aged 54, was educated at the King's School, Rochester, and at Guy's Hospital. At Durham University he graduated in medicine and surgery in 1899 and proceeded to the M.D. degree in 1904, when he obtained the gold medal. After a few years of general practice he joined the R.A.M.C. in 1900 and served successively as specialist in charge of the laboratory at Lucknow, and sanitary officer of the Eastern Command and Burma Division. In 1914 he joined the forces in East Africa as D.A.D.M.S. (San.), G.H.Q., and O.C. Indian Sanitary Section. In 1916 he was appointed D.A.D.M.S., G.H.Q., and in 1917 A.D.M.S. He was mentioned in dispatches four times, created C.M.G., and awarded the D.S.O. Lieut.-Colonel Brown was O.C. Royal Herbert Hospital, Woolwich, from 1919 to 1921, senior M.O. Ceylon Command from 1922 to 1924, and senior M.O. Bordon, from 1925 to 1926, when he retired. He was a Chevalier of the Order of Leopold. Lieut.-Colonel Brown married Pauline, daughter of Mr. F. Normandy, barrister-at-law.

LIVERPOOL HOSPITAL FOR CANCER AND SKIN DISEASES.—This institution is appealing for £100,000 for its reorganisation and the provision of a radium centre and a fully equipped X ray department. It is proposed, among other things, to set aside beds for treatment by radium.

Correspondence.

"Audi alteram partem."

FATALITY-RATES OF SMALL-POX IN THE VACCINATED AND UNVACCINATED.

To the Editor of THE LANCET.

SIR,—Dr. Garrow has drawn attention to the greater relative number of deaths in the vaccinated-over-15 suffering from "mild" small-pox. Many years ago I took out the following figures for the Manchester epidemic of true small-pox for 1903–04.

—	No. of cases.	Deaths.	Fatality per cent.	True hæmorrhagic cases.	Percentage.
Unvaccinated ..	52	10	19·2	1	1·9
Stated to have been vaccinated.					
No cicatrix ..	35	6	17·1	1	2·9 } 4
One mark ..	65	7	10·8	3	4·6 }
More than one mark	362	7	1·9	2	0·6

So far as these figures go they show clearly for true small-pox that the case-mortality is lower the better the vaccination, and they also indicate that doubtful and poor vaccinations (one mark) give a larger percentage of hæmorrhagic cases. My apology for attaching any significance to these small figures is that hæmorrhagic cases are so few, even in a long series.

I assume that only the debilitated die from "mild small-pox." May it not be that the fatal result is due to a smarter initial reaction in the vaccinated and that hæmorrhagic small-pox is due to a similar cause in the inefficiently vaccinated?

I think that it is possible that the further inquiry for which Dr. Garrow presses and which might lead to a better understanding of reaction to infection may actually show (1) that long past vaccination may actually increase the chances of death resulting in the debilitated suffering from mild small-pox, and (2) that inefficient long past vaccination may increase the chances of a hæmorrhagic attack in true small-pox. The inquiry would also emphasise the importance of *efficient* vaccination which modifies the severity of the disease throughout life.

I am, Sir, yours faithfully,

DUNCAN FORBES,
Jan. 20th, 1928. Medical Officer of Health, Brighton.

To the Editor of THE LANCET.

SIR,—My attention has been drawn to a slight error in the tabular statement in my letter of Jan. 14th. The 94 cases in the year 1926 whose vaccination state is classified as doubtful are not included in the figure 3116 as stated in the footnote to the table. This means that the total number of cases for the four years is 10,925 instead of 11,019. This slip does not affect the fatality figures in the vaccinated and unvaccinated.

I am, Sir, yours faithfully,

R. P. GARROW.
Jan. 20th, 1928. Medical Officer of Health, Chesterfield.

THE PRESENT POSITION OF THE VOLUNTARY HOSPITAL.

To the Editor of THE LANCET.

SIR,—Dr. Graham Little does not improve his position. Out of nearly two columns of irrelevancies about his German professor, &c., not in the best of taste, a few things emerge.

He shows that his depreciation of other workers in order to exalt his own circle is not, as one supposed, merely an ignorant habit of mind, but a deliberately chosen line. In the articles in the *Times* to which he refers, he allowed himself to reflect, in a lay journal where he was protected from contradiction, not only upon the abilities, which I am not concerned to discuss, but also, which is unforgiveable, upon the standards of his medical brethren.

Dr. Little quotes without contradiction the statement that "the voluntary hospitals only do 20 per cent. of the work that comes to them," thus admitting one of the most serious defects alleged against the system. He has only two remedies. One is expansion of the voluntary hospitals; whence does he think the extra 80 per cent. of money is to come? The other is to take over those supposed hundreds of empty poor-law beds. In London, at any rate, they do not exist, as he would know well if he knew anything about the subject.

His contention that the voluntary hospitals have become more popular "as compared with other institutions" is palpably absurd, for it is common knowledge, and is indeed the origin of this present discussion, that crowds of patients now gladly enter poor-law hospitals who would never have consented to do so 20 years ago, and that the latter are far more comparable with the voluntary hospitals than was ever the case before.

Is not Dr. Little a politician; or, if he considers the term abusive, is he not, at any rate, a Member of Parliament? How can he really hope that publicly elected bodies would resign the control of their hospitals to a voluntary management? The improbability is obvious, but would take too long to discuss now.

In conclusion, I should like to say that criticism of Dr. Little does not necessarily imply opposition to the voluntary system or to some scheme of coöperation. But the approach will have to be very different from Dr. Little's.—I am, Sir, yours faithfully,

J. C. MUIR,
Medical Superintendent, Whipps Cross Hospital.
Jan. 23rd, 1928. (West Ham Board of Guardians).

THE FUTURE OF MEDICAL PRACTICE.

To the Editor of THE LANCET.

SIR,—I have read with much interest Mr. Somerville Hastings's article (in your issue of Jan. 14th p. 67) on the future of medical practice in England and I should like to make a few observations upon it. So far as the public health service is concerned, it is doing a splendid work for the nation's health, and has undoubtedly come to stay. The same also applies to the venereal disease centres. But it seems to me that other clinics (e.g., tonsil and adenoid, dental, maternity child welfare, &c.) are becoming increasingly unpopular both with the patients and the practitioners. So also are the poor-law hospitals.

The reasons for this unpopularity are not very difficult to trace, because the general practitioner who has charge of the patient after clinic treatment hears the patient's ideas, and is able personally to observe the results of such treatment. I would suggest that this lack of confidence is due to one or more of the following causes:—

1. Bad or incomplete work is done in some clinics. It is sometimes difficult for the practitioners to account for this to the patients without casting reflections upon the medical officer of the clinic concerned.

2. In event of any complication arising as the result of operative work done in a clinic, the patients have to be taken to their family doctor. The actual operator is therefore not available to carry out after-treatment.

3. Attendance at clinics often involves long waits, sometimes in the presence of verminous or even infectious children.

4. Compulsory medical examinations at school sometimes lead to expressions of opinion by the school doctor which differ from opinions previously given by the family practitioner. These occasional conflicts of opinion do much towards weakening faith in school doctors, because the average mother has great faith in her private doctor's opinion, partly because she pays for it, and partly because she considers that "her own doctor *understands* the case."

5. In the case of some poor-law hospitals the principal objection is the exceedingly rude and discourteous way in

which patients (yes, and sometimes practitioners too) are treated by the medical staff. There is also the objection which Mr. Somerville Hastings rightly points out, that no consideration is taken of the practitioner, in that no information is afforded him as to diagnosis and treatment of his patients. These, and other facts, all tend to make institutional centres more unpopular, and their future very uncertain. Many a mother brings her child to me to enucleate its tonsils or to "give it an overhaul" rather than to go to the provided centres.

The truth of the matter is that the general practitioner of to-day is a more all-round efficient man than he was, say, 35 years ago, and this fact alone contributes largely to the improved conditions *re* infant mortality, &c. Public provision *helps* towards this no doubt, but it must be borne in mind that only the poorer people take their children to these centres, whereas infant mortality has improved in the case of the well-to-do as well. This can only be due to the increased efficiency of the family practitioner.

I feel that many practitioners will agree with me that these clinics, &c., are far from popular with many people, and that the chief reason why a large number attend them is because they obtain cod-liver oil, patent milk foods, &c., free, or at a nominal price. It is, in fact, due to the all-too prevalent spirit of the times—the desire to get something for nothing.

I am, Sir, yours faithfully,
J. L. CYRIL DOYLE, M.R.C.S., L.R.C.P.

Harley-street, Jan. 24th, 1928.

MEMORIAL TO DR. JOHN THOMSON.

To the Editor of THE LANCET.

SIR,—Several of the friends and old pupils of the late Dr. John Thomson are anxious to establish some permanent memorial of his great services to pædiatrics in this country and to perpetuate the memory of a very lovable personality. We have been asked to serve as a committee to give effect to this object, and those who are in sympathy with it are invited to send subscriptions to Dr. C. McNeil (44, Heriot-row, Edinburgh) or to Dr. Robert Hutchison (32, Devonshire-place, London, W. 1), who are acting as treasurers. The form of the memorial has not yet been determined and must depend to some extent upon the amount obtained in response to this appeal.—We are, Sir, yours faithfully,

THOS. BARLOW, ROBT. HUTCHISON,
LEONARD FINDLAY, CHARLES MCNEIL,
GEO. F. STILL.

Jan. 18th, 1928.

THE DISPOSITION OF MEDICAL LIBRARIES.

To the Editor of THE LANCET.

SIR,—Your late assistant editor, Dr. H. P. Cholmeley, left me his personal effects, including his books, many of them dealing with medical history. Of these Mr. H. E. Powell, the librarian of the Royal Society of Medicine, made a selection which he wanted for the Society's library, taking 21 works which they had not got, and saying of others that they would "be very useful as second copies, being all interesting works."

There must be an increasing difficulty in securing old books for medical libraries in this country now, on account of the demand in America; within a few days of the announcement of Dr. Cholmeley's death I had an offer to purchase the whole of his library en bloc for an American buyer. This experience has led me to believe that it might be worth while to appeal to your readers to see that our own great libraries, and not only medical libraries, should have a chance of acquiring medical books belonging to deceased doctors.

Even the largest libraries have gaps. For instance, in 1905 I gave about 12 volumes to the Bodleian, mostly eighteenth and seventeenth century historical monographs, none of which they had; and in 1912 I gave a collection of foreign works on medico-social subjects to the Cambridge University Library. Again, the British Museum now has three books which I acquired for practically nothing. One was a volume of Theology printed in Lyons which had belonged to James I. and bore his arms and cypher on the binding; one was the suppressed list of George IV.'s debts, published by William Cobbett; and the third was the last known copy of the Official List of Coaches running out of London in 1832. Such finds may lie ready to the hand of the country doctor. King James's volume was not known to exist outside the Bibliothèque Nationale in Paris.—I am, Sir, yours faithfully,

A. MAUDE.

Forest Edge, Forest Row, Sussex, Jan. 18th, 1928.

MERCUROCHROME INTRAVENOUSLY.

To the Editor of THE LANCET.

SIR,—Two injections prove nothing, but their results may be of sufficient interest to communicate.

CASE 1.—An elderly Brahman with necrosis of the left half of the mandible. He was having frequent rigors and was obviously very ill. An incision over the mandible helped to evacuate the pus and at the same time I gave him 20 c.cm. of 1 per cent. mercurochrome intravenously. The rigors stopped and his condition rapidly improved, so that a few days later I was able to remove the necrotic half of the mandible, after which he made an uninterrupted recovery.

CASE 2.—A large and otherwise healthy European with gonorrhœa and prostatitis of a fortnight's duration. The injection of 20 c.cm. 1 per cent. mercurochrome intravenously was followed in six hours by a severe rigor, the temperature rising to 105° F. and the passage of mercurochrome-stained (i.e., crimson) urine. The moral effect on the patient was terrific, but the therapeutic effect was doubtful.

I am, Sir, yours faithfully,
H. WILLIAMSON,
Capt., I.M.S.

Quetta, India, Jan. 4th, 1928.

"THE CONDUCT OF MEDICAL PRACTICE."

To the Editor of THE LANCET.

SIR,—I have just read this book; it is a book of revelations. Who of the grey-headed amongst us but may wonder as to his ignorance of the many roads open to the young practitioner? No such guide as "The Conduct of Medical Practice" has been available until to-day.

The dean of a medical school is now in close touch with the students in a way that would have astonished and much benefited my generation. I do indeed hope that every dean will study the book and see to it that a reference copy is in the school library wherewith to forestall the chronic heartburn of undigested opportunity.

More than a passing acquaintance with foreign lands encourages me to suggest that a future edition might touch on the facilities and obstacles to general practice in countries other than Great Britain.

I am, Sir, yours faithfully,
FRANCIS POTT.

Florence, Jan. 18th, 1928.

OPERATIONS UPON THE ENLARGED PROSTATE.

To the Editor of THE LANCET.

SIR,—Having had a long and varied experience as an anæsthetist for these operations I think my evidence in support of Mr. Harold Edwards's statements (THE LANCET, Jan. 14th, p. 77) may be worth contributing. These are that exposure to view of the prostatic cavity does not unduly prolong the operation; that shock does not follow the insertion of the bladder retractor; that a varying degree of shock is always associated with prostatectomy, however performed, and is due entirely to the enucleation of the prostate from its bed. As general rules these are in accordance with my observations. In regard to the last, it may be remarked that Mr. Tyrrell Gray and Dr. Parsons showed some years ago that enucleation tends (like dilatation of the sphincter ani) to act as a powerful stimulus, and to be accompanied by a

sudden and marked rise of blood pressure. If enucleation is easy, the patient in fair health, and the anæsthesia or analgesia adequate, effects on the respiration and circulation may be unimportant; otherwise they may fail to respond, and shock in its clinical sense results.

I would add that shock due to stimulation of peripheral nerves must (as always in operations) be carefully distinguished from collapse due to other causes, such as chloroform, intrathecal injection, and emotion in conscious patients.

I am, Sir, yours faithfully,

London, N.W., Jan. 19th, 1928. J. D. MORTIMER.

GASTRO-DUODENAL ULCERATION.

To the Editor of THE LANCET.

SIR,—Presumably Prof. MacLean's duties afford him small opportunity of personal or intellectual contact with the general practitioner. Otherwise he could scarcely do him the injustice of supposing that he prefers to receive his information unbacked by references to the literature and in the form of confident assertion rather than ordered evidence.

In the third paragraph of his paper the following sentence occurs: "We are now satisfied that the results obtained by this method are better than any that have hitherto been described, and that recurrences are extremely rare." Now it would manifestly have been quite impossible in the short space of five years adequately to test all the other methods that have hitherto been described. Furthermore, methods so closely similar to his own as to be identical in action have long been in use, have already found their place in reputable text-books, have been discussed in the journals and at medical societies, and have been shown by others to expedite the healing of ulcers in the way which he now discovers.

Prof. MacLean and his colleagues claim—and no one with experience of the medical treatment of ulcer would question it—that they have cases treated four or five years ago still showing no evidence of recurrence, but they give no indication as to what proportion of cases treated four or five years ago remain healed. This is the kind of information which the thinking practitioner requires and has a right to expect from so authoritative a source as a hospital unit.

My criticism of the claim to "cure" has found unexpected justification, for the undiscerning daily press is already welcoming alkaline treatment as though it were something new and wonderful. In common with Prof. MacLean and many other colleagues I am anxious to see the possibilities of medical treatment in gastric ulcer more widely appreciated in the profession, but for the credit of medicine let us endeavour to ensure that the case is presented fairly, scientifically, and without extravagance. I am, Sir, yours faithfully,

Wimpole-street, W., Jan. 23rd, 1928. J. A. RYLE.

To the Editor of THE LANCET.

SIR,—May we reply very briefly to the letter of Prof. Hugh MacLean and his co-workers in your issue of Jan. 21st? The main purpose of our previous letter was to repudiate the suggestion, inherent in the original article of Prof. MacLean and Drs. Jones and Fildes, that the treatment they outlined was in any essential different from the Sippy treatment, which had long been in extensive use, prior to the date when they state that their investigations were begun. Particularly in view of the echoes which their article has provoked in the lay press, we are happy to note that they now disclaim originality for the method. With regard to our other criticisms and the excellent remarks embodied in the letter of Dr. J. A. Ryle, we are satisfied that time will support our views.

We are, Sir, yours faithfully,

T. IZOD BENNETT.
ALAN MONCRIEFF.

London, W., Jan 23rd, 1928.

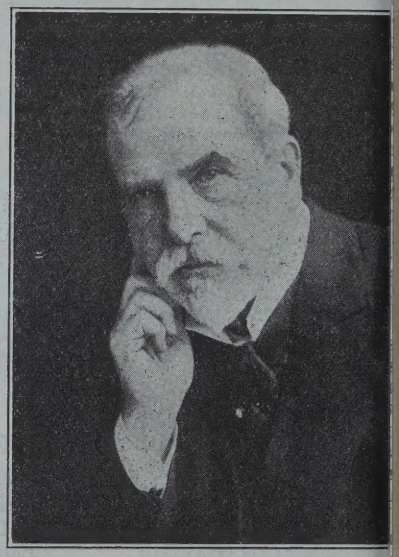
Obituary.

SIR DYCE DUCKWORTH, BART., M.D. EDIN.,

CONSULTING PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL.

WE much regret to record the death, in the eighty-eighth year of his age, of Sir Dyce Duckworth, consulting physician to St. Bartholomew's Hospital, the Seamen's Hospital, and the Italian Hospital, and for many years well known in the consulting circles of London and elsewhere.

Sir Dyce Duckworth was born in November, 1840, the son of Robinson Duckworth, of Liverpool, by his wife, the daughter of Dr. William Nicol, of Stonehaven. He received his early education at the Royal Institution School, Liverpool, and the University of Edinburgh, completing his medical training at St. Bartholomew's Hospital, at the instance of Sir James Paget. He took the diploma of M.R.C.S. in 1862 and graduated at Edinburgh in Medicine in 1863 with the gold medal for medicine, and entered the Navy in the following year as assistant surgeon, but resigned his commission immediately on appointment as medical tutor to St. Bartholomew's Hospital Medical School. He was elected assistant physician to the hospital in 1868, simultaneously with Sir William Church, and F.R.C.P. Lond. in 1870. In 1883 he became full physician, a position which he held for 22 years, retiring in 1905 on attaining the age-limit, when he was appointed consulting physician. Thus he remained on the staff, and in the service of the hospital, either with or without wards, for no less than 40 years.



SIR DYCE DUCKWORTH.

Photograph by Elliott & Fry.

Words from two colleagues show the high appreciation in which he was held by the staff at St. Bartholomew's and its reasons. Dr. James Calvert writes: "Although 23 years have gone since Sir Dyce resigned his office of physician to St. Bartholomew's, until quite recently he was often at the hospital; thus he has never faded from the picture there and his memory is still green. Everyone there will mourn for him and feel sad when they think that never again will they see this very perfect gentleman walk into the square. He just loved the place; in its service he had passed the best years of his most useful and distinguished life. In 1886–87 I was his house-physician—a very happy year for which I must always hold him in grateful remembrance. Sir Dyce was a very good doctor—some great physicians are not good doctors—he was an admirable clinician with an unusual knowledge of drugs and a great belief in their usefulness. No doubt he was somewhat conservative. I think he always rather mistrusted the laboratory, for I remember his invariable advice to the young physician was 'Stick to the bedside.' This advice was considered archaic by many even in those r-off days, but in my opinion it is very sound specially at the present time. Some people have thought that Sir Dyce was 'peppery'; well, he was

n some subjects, but this only made him the more ttractive, while he was too kind-hearted to be really ntolerant. He was devoted to his ward work, very apable, very careful, and above everything else an nduring example to all who worked under him of the onscientious discharge of the duty he had undertaken oth to his patients and to his pupils. He examined ach patient once a week as thoroughly as their ondition allowed, and he required a corresponding xamination and report from the clinical clerk oncerned. Thus, at the end of their three months' lerking his clerks, as the result of much practice, ad a very fair knowledge of physical signs. And hysical signs, on the medical side, appear to me still o be the most important part of a student's training n hospital. His visits to the wards were long and rduous to all concerned—it could not be otherwise onsidering the amount of work he put into them. n a recent occasion I remember he said to me: Character is everything.' Well, I admire and revere ir Dyce Duckworth's character."

Another colleague, of similar standing on the staff, rites: "Sir Dyce Duckworth was a good example f the old style of physician. He began when linical observation and morbid anatomy were almost he only methods of study and when physicians were eldom equipped with the ophthalmoscope and the aryngoscope. He had a good knowledge of skin iseases, but he was interested in the studies of general ervous disorders by which Charcot made such an mpression in the middle of the last century; but the iscoveries of the functions and pathology of the pinal cord and nerves came rather too late to attract is chief attention, which by that time was fixed on he general diseases, such as gout and rheumatism, of hich he was a diligent student, and of the diseases f the heart, lungs, and abdominal viscera. Of these is knowledge was great, and his opinion in such cases as very valuable. He took enormous pains over his ospital work, in which he delighted and visited his ards more often, and in longer visits, than any other hysician. His round, which began at half past one, equently lasted till close upon five o'clock, and a ibald critic once declared that all his house physicians ere afflicted with varicose veins. But he was a lesson o us all in conscientious discharge of duty and for his eal delight in clinical study and practice. For he was great practitioner as well as a great student. He had firm faith in drugs, and he was a far better prescriber han most physicians nowadays are. He sometimes aid that those who disbelieved in drugs did not know ow to use them. It is not certain that he was wrong, hough the fashion was, and is, against him. For the est he was a cultivated man, a good French scholar, nd a most honourable gentleman. He had a great lea of the dignity of his profession, and of the ollege of Physicians, and he was sometimes a little ompous. But there were few who did not like him, nd none who did not respect him.: 'He nothing ommon did or mean.'"

Retirement from daily association with St. Bartholomew's Hospital implied with Duckworth no retirement om active work. In 1907 he was elected physician o the Seamen's Hospital, Greenwich, and in 1910 to hat of the Italian Hospital, so that it is not surprising, aving a wealth of clinical material under his eye or so long a period, that he became well known as a onsultant not only in the particular rheumatic and outy affections with which his name is chiefly ssociated, but in medical cases generally, where he as found sound in diagnosis and resourceful in eatment.

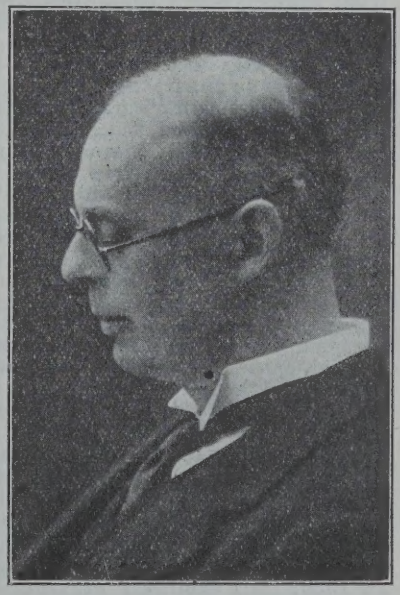
Duckworth's connexion with the Royal College of hysicians of London was a very long and intimate ne. He was a Fellow of the College for 58 years and erved on the Council and on the Censors Board, eing Senior Censor in 1903. He was early singled ut by the College for posts of responsibility, being ppointed treasurer in 1884 and representative of the ollege on the General Medical Council in 1886. The tter post he held for 15 years, while at the time of is death he was emeritus treasurer. In 1896 he delivered the Lumleian lectures on "Sequels of Diseases"; and in 1898 he was Harveian Orator, taking as his subject "Character and Judgment in Medicine." His two deliverances form a close reflection of his personal faith and ideals; they display his high conception of medical ideals, and his trust in authority, human as well as divine, as necessary for right conduct.

On the erection of a Conjoint Board of Examinations under the joint management of the Royal Colleges Duckworth became one of the managers and played an active part in the reforms in education which followed this wise amalgamation of forces. He was the representative of his College, also, as a governor of the University of Liverpool. His services as an examiner were requested by the Universities of Edinburgh, Durham, and Victoria, by the Royal College of Physicians of London, and by the Navy, while he was a medical referee to the Treasury. At different times he received many professional honours, being an hon. M.D. of Cincinnati and the Royal University of Ireland, a member of Convocation of Queen's University, Belfast, and an hon. F.R.C.P. Ireland. He was also LL.D. Edin. and a Knight of Justice of the Order of St. John of Jerusalem. He was knighted in 1886 and shortly afterwards appointed honorary physician to the Prince of Wales, afterwards King Edward VII., and in 1909 was created a baronet. He was a past president of the Clinical Society and a corresponding member of the Académie de Médecine and of the Société Thérapeutique, of Paris, appropriate honours, for he was a fluent speaker of French.

Sir Dyce Duckworth was twice married, first to Annie, widow of the late Mr. John Smith, of Mickleham Hall, Dorking, and secondly to Ada, daughter of Mr. G. A. Fuller, of the Rookery, Dorking, and leaves by his first wife a son, Mr. E. Dyce Duckworth, I.C.S., who succeeds to the baronetcy.

BASIL THORN LANG, B.CHIR. CAMB., F.R.C.S.

Basil Thorn Lang was the only son of Mr. William Lang, consulting surgeon to the Royal London Ophthalmic Hospital and consulting ophthalmic surgeon to the Middlesex Hospital. He was educated at Abbotsholme and Trinity College, Cambridge, and graduated in 1902 with first-class honours in the Natural Science Tripos, completing his general medical education at St. Bartholomew's Hospital. Following in the footsteps of his father, he specialised at once in ophthalmology, working as clinical assistant at "Moorfields" and first as clinical clerk and later as ophthalmic house surgeon at St. Bartholomew's. In order to gain operative experience he went to India for six months and studied under Colonel Henry Smith at Jullundur and under Colonel R. H. Elliot at Madras, thus becoming a dexterous operator.



MR. BASIL LANG.

Photograph by Stuart.

Colonel Smith writes: "I came to know Mr. Basil Lang as a guest in my house and at my hospital

at Amritsar. During that time we discussed a wide range of things scientific and others, and I then came to the conclusion, since confirmed, that he was a man of exceptional ability with a wealth of information and with fearless moral courage. In difficult cases of refraction he had very few equals. Cases came to me often as a sort of last hope, each with a pocket full of glasses and diagnoses down to and including the early stage of cataract. I am not a refractionist and I sent the patients on to Mr. Lang. In every case his first glasses acted as a charm, and I received letters of thanks from the patients saying that they had been relieved of all their worries. In other fields he was equally brilliant, and the ophthalmic section of our profession has suffered a great loss in his death."

At the outset of the war he at once joined the R.A.M.C. and served practically continuously in France throughout the hostilities. At first he devoted his energies to X ray work, and by means of his inventive gifts, combined with his technical knowledge, he devised and built in France the first mobile X ray unit for use in the front areas; when the King met with his serious accident, Lang and his unit were immediately sent for to X ray His Majesty. Shortly after a serious illness led to his being invalided home for several weeks, and from this he probably never completely recovered; but on returning to duty he became ophthalmic specialist and did valuable work both at Rouen and Etaples. An enthusiastic photographer, he did some excellent colour plates of trench feet, and his X ray work is well described in the following note from a military co-worker:—

G. T. L. writes: "Early in 1915 I found Basil Lang at Rouen, busy as X ray specialist to No. 8 General Hospital. Although 'eyes' were his specialty, he was an adept at X ray work, and his department was extraordinarily well run and full of ingenious devices and self-made improvements on the regulation X ray apparatus. He was a very great help to me in the rapid X ray localisation of foreign bodies in the eye—my unit took in all the eye wounds. His spare time was spent in making friends with French doctors and civilians, always with a view to devising some new apparatus or improving an old one, not only for radiological, but for surgical and ophthalmic use as well. Often one would meet him emerging from some obscure back street with a grin on his face, and his great voice would boom out and tell you how he had just unearthed and befriended a workman who would make for him some special instrument or apparatus. He had made a wonderful series of colour photographs of trench feet, for he had quickly realised the need of X rays nearer the fighting line. With characteristic energy he raised funds, designed, and had made a travelling, self-contained X ray lorry; this entailed a vast amount of work, first to obtain official sanction, and then to get the unit made. Many visits to Paris were necessary for the special electrical apparatus, but in the autumn Lang went up the line in charge of No. 1 mobile X ray unit, which he used later to examine the King after his fall from a horse. His carrying out of the idea was original and, as events proved, extremely useful; it was adopted later by the War Office, though the pattern was not exactly copied, as French apparatus had been used. It was at times such as this that one realised the extraordinary mental and physical energy of Basil Lang; he was always striving after something better."

After the war he was appointed assistant surgeon to the Western Ophthalmic Hospital and Lang Research Scholar, posts which he held till his election to the staff of the Royal London Ophthalmic Hospital in 1920. No summary of Lang's medical achievements would give a clue to the versatility or brightness of his intellectual activities. Having a clear and broad grasp of the principles of physics as well as a gift for constructive detail, he understood the diverse practical working of motor-cars, the telephone, the wireless, as well as the various optical instruments. Consequently he welcomed enthusiastically any clever invention—and he himself devised ma several of which he patented, one of the most nota being a long distance range-finder. He had origi methods both of treatment and operating, and sho considerable resource. He invented several ingeni ophthalmic instruments, chiefly various forms perimeter and an operating lamp, and he deligh in any new type of apparatus which extended to ophthalmic surgeon further powers of observati This is well shown in his writings—in his book, Routine Examination of the Eye (an amplif edition of his father's excellent handbook— Methodical Examination of the Eye) and in papers on perimetry and scotometry; all these sh his capacity for minute observation and his original of thought. With such a versatile and active m it was felt generally that he was capable of work far-reaching value, and the cutting short of his life its prime is, from a professional point of view tragedy.

An intimate friend writes: "His outstand feature was his ebullient vitality and quickness mind, combined with a good nature which, wh roused, could be genuinely quixotic. A large numb of friends, who fell under the spell of his refresh vitality, will feel his loss deeply, while his chee forgiving nature—proof against opposition or rebuf will have saved him from having made a sin enemy." And from Mr. Basil Lang's chief assist at Moorfields we have received the following tribu endorsed by his house surgeons: "It is difficult imagine a more refreshing and a more stimulati chief than Mr. Basil Lang. His exceptional knowled of physics combined with an unconventional gc humour and a cheerful readiness to give an opini always apposite, which would help to solve a probl or throw light upon a controversy, made him a teach of great value and a companion of exceptional char Every question of interest which came under d cussion had been considered by him from a viewpo just a little different from that of others, and he wo offer a reasoned argument built on sound knowled In the operating theatre his personality fou expression in his generosity to the house surgeo in the instruments he used, in the operations performed, and in the views and ideas he discuss between cases. He had a profound respect for t evils consequent upon having capsule in the wou of his cataracts and almost invariably did sim extractions followed by an anterior chamber wash-o For glaucoma he preferred Lagrange's operation, o modification of it, to trephining, and he frequen did Herbert's sclerotomy. A picturesque feature his work was his use of green towels to avoid distracti glare. He was an operator of real skill, but it probable that his greatest pleasure was in t examination and treatment of his out-patients. W who, either 'upstairs or down,' worked under h at Moorfields, feel that by his death we have lost r only a friend but a rare and valued source of kno ledge and new ideas."

Basil Lang's activities were much impaired some two years before his death with arthrit which laid him up for weeks at a time; yet he bo his disabilities with never a complaint and with t utmost pluck, while every form of new treatme was tried with astonishing optimism.

He was only married 11 months ago, and all w knew him will offer his widow, his father, and sist their deep sympathy in the irreparable loss th have sustained.

THOMAS TOMBLESON BRUNYATE, M.D. OXF.

IT is with regret that we record the death of T. T. Brunyate, which occurred on Jan. 1st, Chaucer's House, Woodstock, in the 61st year his age.

Brunyate was educated privately and at Oxfo where he was a scholar at Christ Church, having special aptitude for mathematics, which was a fami

rait. From Oxford he won an entrance scholarship t St. Mary's Hospital in natural science, and was ventually house physician in this hospital. He took he M.B. and B.Ch. Oxf. in 1892, and the M.D. degree 1 1894. In addition to attaining academic distinction e was a cultivated man in the widest sense and one f outstanding ability; he was obviously fitted for ome of the higher branches of his profession, and yet e deliberately chose the career of the country doctor, choice which neither he nor any concerned had ver any reason to regret. He practised first in Rochester, and became physician to St. Bartholo-new's Hospital in that city. Then, some 20 years go, he removed to Woodstock, attracted by its earness to his University. There he continued to he end, showing by his life the full possibilities of is calling and its adequate scope for applying cientific attainment with the utmost human interest. He was an ardent lover of Nature and of the simple hings of life. He was a good oar in his day, and a ood golfer and tennis player to the end, and also a ood teacher of these as well as of mathematics, s the prowess of his children in several directions as made clear. (Take tennis as an instance, his wo daughters have representative colours both for he University and for the County of Oxford.) He lways took a keen interest in his University and that f his children, and participated in the post-graduate ork connected with the Radcliffe Infirmary; one on and one daughter are already engaged in the study f medicine. A colleague writes: "Brunyate was man of high integrity which, added to his ability nd humanity, gained him the respect and admiration f the whole neighbourhood in which he lived and orked. To his widow and children the utmost ympathy will be extended with the assurance that he works of her husband's fine life are even now ollowing him and will continue to do so."

His death called forth an extraordinary manifestation of respect and affection from a wide area, including, ut far outreaching, his own home district.

THEOBALD ADRIAN PALM, M.D. EDIN.

To Dr. Adrian Palm, whose death has occurred at Aylesford, belongs the credit of having set out as ong ago as 1890 the view that rickets is due to leprivation of sunlight. His communication to the *Practitioner* in that year on the Geographical Distribution and Ætiology of Rickets unfortunately attracted ittle notice, and his suggestion was only recalled when he investigations of other workers had established he relation which he postulated. Born at Colombo nearly 80 years ago, he was the son and grandson of Presbyterian missionaries. He graduated in arts at he University of Edinburgh in 1867 and in medicine ix years later, and after a short spell as resident nedical officer to the Cowgate Dispensary he followed he family tradition by going out to Japan, for the Edinburgh Medical Missionary Society, to the Niigata Mission Hospital. There he remained ten years and made many observations on the customs and diseases of the population, some being contained n a work entitled "Kakke: A Study of Disease in Japan," and others in reports to English and Scottish nedical journals. Returning to this country he took up general practice at Wigton and was appointed nedical officer of health for the Wigton Urban District. Twenty-three years ago Dr. Palm moved o Aylesford in Kent, where he lived until his death, and in 1924, in recognition of his early observations on rickets, he was elected president of the newly formed Sunlight League. Whilst in Japan he married Miss Collas, of Jersey, who was also engaged in missionary work.

NORTH STAFFORDSHIRE ROYAL INFIRMARY.—During he past year workmen's contributions to the Stoke-on-Trent Hospital amounted to £27,681, which is £600 above he "record" achieved in 1925.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 14TH, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 398 (last week 275); scarlet fever, 1733; diphtheria, 1306; enteric fever, 48; pneumonia, 2108; puerperal fever, 54; puerperal pyrexia, 126; cerebro-spinal fever, 9; acute poliomyelitis, 7; acute polio-encephalitis, 3; encephalitis lethargica, 25; continued fever, 1; dysentery, 12; ophthalmia neonatorum, 118. There was no case of cholera, plague, or typhus fever notified during the week.

The cases of small-pox were notified from 18 counties—viz., Bedford 1 (Bedford), Derby 15, Durham 71, Isle of Ely 4, Lancaster 30, Leicester 3, Lincoln, Parts of Lindsey 7 (Lincoln C.B.), Northampton 1 (Kettering), Northumberland 14, Nottingham 14, Stafford 2, Sussex West 4, Warwick 19, Yorks North Riding 12, West Riding 87, Brecknock 21, Glamorgan 36, Monmouth 57.

Since this return was made up ten cases of small-pox have been reported from Barnet and isolated at Cheshunt. Six of these were patients and one a nurse in the Wellhouse Poor-Law Hospital; the remaining three were children at the Guy's Cliff cottage homes.

In view of the number of cases of small-pox reported among casuals from different parts of the country, the Minister of Health has directed poor-law medical officers from now until March 31st to examine all casuals on admission to the workhouse, stripping them to the waist for efficient inspection.

Deaths.—In the aggregate of great towns, including London, there was no death from small-pox or enteric fever, 91 (31) from measles, 7 (2) from scarlet fever, 23 (4) from whooping-cough, 48 (7) from diphtheria, 61 (11) from diarrhœa and enteritis under two years, and 145 (16) from influenza. The figures in parentheses are those for London itself. Of the 60 fatal cases of measles outside London 11 were reported from Bristol, 18 from Manchester, 1 from Salford, 4 each from Croydon and Brighton; while the figures from Glasgow and Dublin for the same week were 46 and 11 respectively. The number of stillbirths registered during the week was 300 in the great towns, including 49 in London.

The death from small-pox reported in last week's return from Bradford occurred in the North Bierley Institution, Clayton, just outside the county borough boundary. The cause of death was certified by the medical officer in charge as: (*a*) myocarditis, (*b*) senility, (*c*) small-pox. There was no evidence of the patient having been vaccinated.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—On Monday, Jan. 30th, at 5 P.M., at the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, W. 1, Dr. Vincent Coates will lecture on the Principles of Spa Treatment. On Jan. 31st, at 10 A.M., at the Brompton Hospital for Consumption, Dr. Burrell will give a clinical demonstration, and on Feb. 2nd, at 2 P.M., at the Royal National Orthopædic Hospital, Mr. W. H. Trethowan will demonstrate. On Feb. 3rd, at 5 P.M., at the Royal Westminster Ophthalmic Hospital, Mr. W. H. McMullen will give a lecture-demonstration on Lacrymation: Its Causes and Treatment. The lecture and demonstrations are open to members of the medical profession without fee. From Jan. 30th to Feb. 25th a course will be held at the London School of Dermatology (St. John's Hospital); clinical instruction will be given in the out-patient department every day and lectures on Tuesdays and Thursdays, at 5 P.M. (practical pathological demonstrations can also be arranged). From Feb. 6th, for four weeks, a course in Venereal Disease will be given at the London Lock Hospital during the afternoons and evenings, consisting of clinical instruction and lectures. From Feb. 6th to 18th a course in Diseases of Children will be given at the Paddington Green Children's Hospital and the Victoria Hospital for Children. From Feb. 20th to March 3rd, at the Queen Mary's Hospital, Stratford, an all-day course will be given in medicine, surgery, and the specialties. The entire practice of the hospital will be open to those taking the course. From Jan. 30th to March 23rd, at the National Hospital, Queen-square, a course will be held in neurology, anatomy, and physiology of the nervous system, and demonstrations will be given in methods of examination and in pathology. Information, syllabuses, tickets, and copies of the *Post-Graduate Medical Journal* may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W.

Medical News.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—The following candidates have passed the Triple Qualification Examination:—

FINAL EXAMINATION.

M. O. Chacko, P. G. Sawmy, H. F. N. Slane, E. E. M. Steen, E. S. R. Menon, W. W. McGlashan, R. G. Paranjape, J. B. Forrester, S. E. W. Boland, V. Sinnetamby, S. T. Sodah, Sinnathamby Chelliah, F. H. Emery, J. H. M. Beck, Bangalore Jaya Ram, James Masilamani, W. B. Russell, A. G. Smith, N. C. Dasgupta, A. M. Boyne, H. C. Furst, E. P. N. Abeyesundere, B. J. Ess, J. E. D. Mendis, G. R. Gardner, J. M. Chittambalam, Maurice Klar, K. L. Palit, F. W. Raysmith, J. C. Anders, and J. E. Felix.

UNIVERSITY OF WALES.—The following candidates have satisfied the examiners:—

M.B., B.CH.

Medicine, Surgery, and Obstetrics—John H. Williams, William G. Evans, and Trevor R. Bryant.

UNIVERSITY OF LONDON: *University College Hospital Medical School.*—Applications are invited for the Radcliffe Crocker travelling scholarship in dermatology, which is worth about £280, and is tenable for 12 months, to be spent in a place of study outside the United Kingdom.

London School of Hygiene and Tropical Medicine.—A research studentship in protozoology is offered at this school. It will in general be held for two years, and remuneration is at the rate of £250 a year. Details of both these appointments will be found in our advertisement column.

UNIVERSITY COLLEGE HOSPITAL, LONDON.—Dr A. F. Tredgold, who has been appointed an associate physician of the hospital in psychological medicine, will hold a special clinic for conditions of delayed and incomplete mental development or alternatively for cases of mental deficiency, retardation, and allied conditions, the clinic being the first of its kind to be established at a hospital with a medical school. The new clinic will not only afford opportunities for students to gain a knowledge of mental deficiency and allied conditions but will, it is hoped, constitute a further step towards bringing psychological medicine into touch with general medicine. The clinic will be held in the out-patient department of the hospital on Thursdays at 11 A.M., commencing Feb. 2nd.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—The Hunterian Oration will be delivered at the College by Sir Holburt Waring on Tuesday, Feb. 14th, at 4 P.M. Fellows and Members of the College are invited to attend.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION.—The annual general meeting of this association is to be held at 11, Chandos-street, London, W., on Friday, Feb. 10th, at 5 P.M. (tea 4.30 P.M.), when Dr. A. A. Mumford will read a paper on the School Medical Officer of the Future.

EUGENICS SOCIETY.—The Galton anniversary dinner will be held at the Rembrandt Hotel, Brompton-road, S.W., on Thursday, Feb. 16th, at 7.15 P.M. The Galton lecture will be delivered by Mr. C. J. Bond, F.R.C.S., whose subject will be the Distribution of Natural Capacity in the Population and the Need for National Stock-taking.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—The College will be closed during the month of February for internal painting and decorating.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.—The Maternity and Child Welfare Group is meeting this week-end at Edinburgh under the presidency of Dr. E. H. T. Nash, with the support of Mr. Alexander Miles, President of the Royal College of Surgeons of Edinburgh, and Dr. W. Robertson, medical officer of health for the city. To-day (Saturday) there will be a clinical meeting at Pilton Hospital, with a lecture demonstration on congenital syphilis by Dr. David Lees at 10.30 A.M., and two afternoon sessions (2.30 to 4 P.M.) will be held at the Royal Hospital for Sick Children and the City Fever Hospital, when papers will be read by Prof. Leonard Findlay, Dr. Chas. McNeil, Prof. John Fraser, Mr. D. S. Middleton, Dr. J. A. Stephen, and Dr. T. Y. Finlay.

As the report of the Departmental Committee on Vaccination has not yet been published the discussion on the Control of Small-pox, arranged by the society for Feb. 17th, is postponed until Friday, March 16th. The next council meeting of the society is also postponed until the latter date.

ROYAL LONDON OPHTHALMIC HOSPITAL.—The annual dinner of past and present students will be held at the Langham Hotel, Portland-place, W., on Wednesday, Feb. 8th, at 7 for 7.30 P.M. Sir Wilmot Herringham will take the chair. The secretary is Sir William Lister, 24, Devonshire-place, London, W.

THE fifteenth annual post-graduate week for midwives, arranged by the General Lying-in Hospital, York-road, London, S.E., will be held from May 21st to 25th. Names should be sent to the secretary, Post-Graduate Week, c/o the Hospital.

TRUE TEMPERANCE ASSOCIATION.—The annual meeting will be held at the Caxton Hall, Westminster, on Monday, Jan. 30th, at 5 P.M. Lord Lamington will take the chair and Sir William Arbuthnot Lane will be one of the speakers.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

WEDNESDAY, Feb. 1st.—5 P.M., HISTORY OF MEDICINE. Papers: Dr. G. A. Auden: (1) The Gild of the Barber Surgeons of the City of York. (2) Note on an Ancient Medical Manuscript in the Library of York Minster. 8.30 P.M., SURGERY. Pathological Evening.

THURSDAY.—8.15 P.M., TROPICAL DISEASES. Discussion on Life Assurance in the Tropics. Opened by Sir William Prout, followed by Mr. H. E. Raynes, Dr. J. F. C. Haslam, and others.

FRIDAY.—5 P.M., LARYNGOLOGY. (Cases at 4 P.M.) Cases and Specimens will be shown by Mr. Norman Patterson, Dr. Dan McKenzie, Sir James Dundas-Grant, Mr. Ridout, Dr. Jobson Horne, Mr. Barwell, and others. 8.30 P.M., ANÆSTHETICS. Paper: Mr. A. Douglas Cowburn: Death occurring under Operation, or Before Recovery from Anæsthesia.

SATURDAY.—10.30 A.M., OTOLOGY. (Cases at 9.30 A.M.) Papers: Dr. Alexander Fleming: The Bactericidal Power of the Blood and Methods of Altering it. Dr. A. Lowndes Yates: Methods of Estimating Alteration in the Middle Ear by Means of Quantitative Tests of Hearing. (Demonstration of audiograph.) Cases and specimens will be shown by Sir James Dundas-Grant, Dr. H. Norman Barnett, Mr. H. J. Banks-Davis, Mr. C. Hamblen Thomas, and others.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Jan. 30th, to SATURDAY, Feb. 4th.—FELLOWSHIP OF MEDICINE LECTURE at the Medical Society of London, 11, Chandos-street, Cavendish-square, W. Mon., 5 P.M., Dr. Vincent Coates: The Principles of Spa Treatment.—BROMPTON HOSPITAL FOR CHEST DISEASES, Brompton. Mon., 10 A.M., Clinical Demonstration by Dr. L. S. Burrell.—ROYAL NATIONAL ORTHOPÆDIC HOSPITAL, 234, Great Portland-street, W. Thurs., 2 P.M., Mr. W. H. Trethowan: Special Clinical Demonstration.—ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Charing Cross, W.C. Fri., 5 P.M., Mr. W. H. McMullen: Lecture-demonstration—Lacrimation: Its Causes and Treatment.—BETHLEM ROYAL HOSPITAL, St. George's Fields, S.E. Course in Psychological Medicine. Lecture-demonstrations Tues. and Sat., 11 A.M.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, W.

MONDAY, Jan. 30th.—10 A.M., Dr. Dowling: Skin Department. 11 A.M., Mr. Tyrrell Gray: Surgical Wards. 2 P.M., Dr. Trevor Davies: Gynæcological Department.

TUESDAY.—2 P.M., Dr. Shaw: Medical Out-patients. 2 P.M., Mr. Sinclair: Surgical Out-patients. 2 P.M., Mr. Hamblen Thomas: Throat, Nose and Ear Department.

WEDNESDAY, Feb. 1st.—10 A.M., Dr. Burnford: Medical Wards. 2 P.M., Mr. Tyrrell Gray: Operations. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart: Neurological Department. 2 P.M., Mr. MacDonald: Genito-urinary Department. 2 P.M., Mr. Bishop Harman: Eye Department.

FRIDAY.—10 A.M., Dr. Pritchard: Special Medical Treatment Clinic. 2 P.M., Mr. Vlasto: Throat, Nose and Ear Department. 2 P.M., Dr. Shaw: Medical Out-patients.

SATURDAY.—10 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Owen: Medical Diseases of Children.

Medical and Surgical Out-patients, Operations, Special Departments, daily, 10 A.M. to 5 P.M., Saturdays, 10 A.M. to 1 P.M.

NORTH-EAST LONDON POST-GRADUATE COLLEGE, Prince of Wales's General Hospital, Tottenham.

MONDAY, Jan. 30th.—2.30 to 5 P.M., Medical, Surgical, and Gynæcological Clinics. Operations.

TUESDAY.—2.30 to 5 P.M., Medical, Surgical, Throat, Nose and Ear Clinics. Operations.

WEDNESDAY, Feb. 1st.—2.30 to 5 P.M., Medical, Skin, and Eye Clinics. Operations.

THURSDAY.—11.30 A.M., Dental Clinics. 2.30 to 5 P.M., Medical, Surgical, and Ear, Nose and Throat Clinics. Operations.

FRIDAY.—10.30 A.M., Throat, Nose and Ear Clinics. 2.30 to 5 P.M., Surgical, Medical, and Children's Diseases Clinics. Operations.

PEOPLE'S LEAGUE OF HEALTH.

THURSDAY, Feb. 2nd.—6 P.M. (at the Medical Society's Rooms, 11, Chandos-street, Cavendish-square, W.), Dr. E. D. Macnamara: Primitive Instinct.

ST. PAUL'S HOSPITAL, Endell-street, W.C.

THURSDAY, Feb. 2nd.—4.30 P.M., Mr. Frank Kidd: Some New Devices in Urinary Surgery.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Jan. 31st.—5 P.M., Dr. S. E. Dore: Alopecia.

THURSDAY, Feb. 2nd.—5 P.M., Dr. A. M. H. Gray: Xanthoma. Herpes.

CENTRAL LONDON THROAT, NOSE AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Jan. 30th.—1.30 P.M., Mr. R. J. Cann: Examination of the Accessory Sinuses.

WEDNESDAY, Feb. 1st.—1.30 P.M., Mr. N. MacKeith: Examination of the Larynx.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Jan. 31st.—3.15 P.M., Dr. R. Wade: Anæsthesia.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street W.C.

THURSDAY, Feb. 2nd.—4 P.M., Dr. Poynton: Some Features in Respiratory Diseases in Child and Adult.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

WEDNESDAY, Feb. 1st.—4.30 P.M., Dr. Nathan Raw: Medico-Legal Problems of Lunacy.

UNIVERSITY OF SHEFFIELD POST-GRADUATE CLINICS.

FRIDAY, Feb. 3rd.—3.30 P.M., Dr. Barnes: Clinical Cases.

ST. MARY'S HOSPITALS, MANCHESTER (Post-Graduate Lecture).

FRIDAY, Feb. 3rd.—4.30 P.M. (at the Whitworth-street West Branch), Dr. Dougal: Occipito-posterior Positions.

Appointments.

REMMELL, R. W., M.D. Liverp., D.P.H., has been appointed Hon. Radiologist to the David Lewis Northern Hospital, Liverpool.

INGRAM, J. T., M.D., M.R.C.P. Lond., Lecturer in Diseases of the Skin to the University of Leeds.

RADFORD, MAITLAND, M.D., B.S. Lond., D.P.H., Medical Officer of Health for Shoreditch.

STEEL, R., M.B., Ch.B. Glasg., Hon. Radiologist at Southport Infirmary.

Certifying Surgeons under the Factory and Workshop Acts, O'SULLIVAN, A. J., L.A.H. Dub. (Roade District of the County of Northampton); DODGSON, H., M.B., Ch.B. Edin. (Folkestone District of the County of Kent).

Vacancies.

For further information refer to the advertisement columns.

All Saints' Hospital for Genito-Urinary Diseases, 91, Finchley-road, N.W.—Hon. Consulting Phys. and Hon. Surg. Reg.

Bradford County Hospital.—Asst. H.S. At rate of £130.

Brierfield General Hospital.—H.P. £150. Also Hon. Orthopædic S.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.

Bristol, Royal Hospital for Sick Children and Women.—Hon. P. to Out-patients.

Calcutta, Presidency College.—Prof. in Physiology. Rs.800 per month.

Calcutta School of Tropical Medicine.—Research Worker Rs.1750.

Cambridge, Addenbrooke's Hospital.—H.P. At rate of £130.

Cardiff Royal Infirmary.—Hon. Asst. Surg. to Ear, Nose, and Throat Department.

City of London Hospital for Diseases of Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

City of London Maternity Hospital, City-road, E.C.—Registrar. £100.

Dewsbury and District General Infirmary.—H.S. £200.

Edinburgh, East Fortune Sanatorium.—Asst. M.O. £250.

Elizabeth Garrett Anderson Hospital.—Asst. Radiologist. £100. Also Asst. Pathologist. £150. Both part-time.

Great Yarmouth, General Hospital.—H.S. £150.

Hertford County Hospital.—Hon. Asst. S.

His Majesty's Indian Medical Service.—Appointments.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—Hon. Asst. P.

Hospital for Women, Soho-square, W.—Hon. Med. O. to Out-patients.

Hull Royal Infirmary.—Cas. H.S. At rate of £130.

Ilford Emergency Hospital, Essex.—Jun. H.S. £90.

Leicester Royal Infirmary.—Hon. P. and Asst. Hon. P. Asst. Pathologist. £500. Also Cas. H.S. At rate of £125.

Liverpool, City of.—City Coroner. £1000.

London School of Hygiene and Tropical Medicine, 23, Endsleigh-gardens, W.C.—University Chair of Public Health. £1500. Also Research Studentship in Protozoology. £250.

Margate, Princess Mary's Hospital for Children.—Second Asst. M.O. £550.

Middlesbrough County Borough.—Asst. to M.O.H. £450.

Mount Vernon Hospital, 7, Fitzroy-square, W.—Asst. P.

Preston County Borough.—Asst. S.M.O. £600.

Queen Mary's Hospital for the East End, E.—Anæsthetist. 25 guineas.

Royal London Ophthalmic Hospital, City-road, E.C.—Asst. Surg.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. M.O. and Asst. Res. M.O. At rate of £175 and £130 respectively.

St. Thomas's Hospital.—Phys. in charge of Out-patients.

Sheffield Royal Infirmary.—Hon. Asst. Ophth. S.

Shoreditch, Metropolitan Borough of.—Asst. M.O.H. £650.

Sleaford, Kesteven Mental Hospital.—Asst. M.O. £350.

Smethwick County Borough.—Asst. M.O.H., &c. £600.

Stoke-on-Trent City Maternity Home.—Res. M.O. £450. Also Consulting Officer. £150.

Truro, Royal Cornwall Infirmary.—H.S. £170.

University College Hospital Medical School.—Radcliffe Crocker Travelling Scholarship in Dermatology. £280.

West London Hospital, Hammersmith-road, W.—Hon. Obstet Reg.

West Riding County Council.—School Oculist. £600.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

The Chief Inspector of Factories announces the following vacant appointments for Certifying Factory Surgeons: Hipperholme (York, West Riding), Cirencester (Gloucestershire), Peasenhall (Suffolk), Pontrhydygroes (Cardiganshire), Chester (Cheshire), Fort William (Inverness-shire), Inverurie (Aberdeenshire), and Uckfield (Sussex).

The Secretary of State for the Home Department gives notice of vacancies for one or more Ophthalmic Specialist Medical Referees under the Workmen's Compensation Act for County Courts in circuits comprising roughly the East Riding of Yorkshire and Lincolnshire. A vacancy is also announced in Circuit No. 55, Bridport, Dorchester, &c. Applications should reach the Private Secretary, Home Office, London, S.W., not later than Feb. 7th and 10th respectively.

Births, Marriages, and Deaths.

BIRTHS.

BILDERBECK.—On Jan. 19th, at a nursing home, Littlehampton, Sussex, the wife of Major Bilderbeck, I.M.S., of a son.

EDWARDS.—On Jan. 22nd, the wife of A. Tudor Edwards, F.R.C.S., of Queen Anne-street, Cavendish-square, of a daughter (stillborn).

JONES.—On Jan. 19th, at Royal Naval Hospital, Haslar, the wife of Surgeon-Commander Lloyd Jones, of a daughter.

MARRIAGES.

CARDELL—CRAIG.—On Jan. 21st, at All Saints Church, Kenley, Surrey, John Douglas Magor Cardell, M.B., B.S., F.R.C.S., to Audrey Winifred, elder daughter of Lieut.-Colonel James Craig, C.B., and Mrs. Craig, The Glen, Kenley, Surrey.

DEATHS.

BROWN.—On Jan. 21st, Lieut.-Colonel R. Tilbury Brown, late R.A.M.C., aged 54.

DUCKWORTH.—On Jan. 20th, at Grosvenor-place, S.W., Sir Dyce Duckworth, Bart., M.D., LL.D., F.R.C.P., aged 87.

HENRY.—On Jan. 16th, at Clones, suddenly, from pneumonia, William Henry, M.B.

LANG.—On Jan. 18th, Basil Thorn Lang, F.R.C.S., Surgeon to the Royal London Ophthalmic Hospital, Moorfields, aged 47 years.

RIDDELL.—On Jan. 19th, very suddenly, Brownlow Riddell, O.B.E., M.D., Newton-place, Glasgow, aged 58 years.

SABERTON.—On Jan. 16th, at Forest-road, Bournemouth Claude William Scott Saberton, M.D., D.M.R.E. Camb.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

A VITA-GLASS PAVILION.

Dr. T. C. Hunter writes to call our attention to a pavilion, the first of its kind he believes, at the Stannington Sanatorium for Consumptive Children, Morpeth, of which he is medical superintendent. Owing to its relative impermeability to ultra-violet rays ordinary glass cannot profitably be used to shelter patients undergoing sun and fresh-air treatment for tuberculosis. With the invention of a glass which has the property of transmitting a considerably greater portion of these rays, hundreds of hours of sunshine can now be utilised which otherwise would be lost owing to the Spartan character of the climate. "I do not know what is the experience of other observers," Dr. Hunter writes, "but in our opinion the artificial rays are not comparable with the natural sunlight for healing purposes and our recoveries are immeasurably quicker and more certain with the latter agent, though we use both extensively. Moreover, a larg proportion of cases can be so treated." The pavilio 70 by 25 feet, is composed entirely of vita-glass exceptir for certain small offices in wooden framework. Ventilatic on boisterous days is provided for by a large lantern whi can be opened along its entire length, north and sout The whole of the southern and half of the northern fro can be opened by means of folding windows on ball bearing which slide along and fold up and back. The buildi was designed to accommodate 50 patients in special reclini chairs such as are extensively used at Swiss health resort By this means the most delicate patients, whose powers resistance are small, can take their light and air with litt

The Stannington Vita-glass Pavilion.

drain on their combustion. "Only those who have soug their cure on draughty balconies and verandahs," I Hunter remarks, "can fully appreciate this boon." T glass costs several times the price of ordinary glass, and t money was given by an anonymous donor for the spec purpose. The reproduced photograph shows the inter of the pavilion with patients undergoing treatment.

A HOSPITAL PHARMACOPŒIA.

THE pharmacopœia of the Great Ormond-street Hospital has a value which extends considerably beyond its primary purpose. The experience that comes of collating results obtained from a large number of cases is here placed at the disposal of practitioners whose observations of children's ailments are relatively few and scattered. Classified formulas occupy hardly more than half the total space of 83 pages; doses of internal medicines have been adjusted to those suitable for children 1 year old, and formulas differing from those with identical titles in the British Pharmacopœia bear an indication of the fact. Diet tables are divided into five age-periods, beginning at six months and ending at seven years; in addition there will be found a milk-water-sugar table for young infants, quantities for a typical week's dinner for children 7 years old, and a list of diet ingredients. The Medical Committee has recently (July 6th, 1927) revised its food recipes, its directions for the care of rickety children, for tending paralysed children, for cleaning the teeth, and so forth; these sections follow the memoranda on diet. Other features include Holt's table of weight, height, and circumference to the twelfth year, quarantine and incubation periods, and lists of thermometric and other equivalents. The book is provided with an index of titles and an index of drugs. The new edition, revised by Mr. J. Wicliffe Peck, F.C.S., is printed for private use under the authority of the Hospital Committee, and copies are obtainable on application to the Secretary of the hospital.

A PLEA FOR A EUGENIC SETTLEMENT.

THE author of a book entitled the Survival of the Unfittest (Charles Wicksteed Armstrong. London: C. W. Daniel Company. Pp. 160. 6s.) is a widely travelled man, who recognises in modern democracy a threat to this country and to the white races. In the competition for votes which is a sine qua non of party Government, in the National Insurance Act, in the "dole," and in indiscrimin charity are seen means by which the unfit are preserv and encouraged to multiply, while the biologically fit handicapped. It is suggested that if the necessary fun can be raised, a eugenic settlement be founded wher only those of established physical and mental excelle be admitted. The author's ideas emerge from a cohere system of social and biological theory, which, wh likely to provoke disagreement, bespeaks original a vigorous thought. The book would be read with pr by those medical men unfamiliar with the aims a principles of eugenics.

CYSTIC PNEUMATOSIS OF THE BOWEL.

F.R.C.S. Edin. writes: "May I call the attention Dr. J. Silverstone, whose paper on cystic pneumatosis the bowel appears in your issue of Jan. 21st, to the f that in addition to the three time-worn and not altogeth satisfactory theories of causation which he mentions th is a third theory—the *chemical*—which has been advanc by Prof. P. Masson, of Strasbourg. This theory has received the attention it deserves in this country. It much more satisfying and logical than any of the th theories Dr. Silverstone, following precent, quotes. T argument will be found in extenso in Ann. d'anat. path et d'anat. normale médico-chirurg., Paris, 1925, ii., 541.

PLASMOCHIN OR PLASMOQUINE.

To the new synthetic remedy for malaria, introduced the Düsseldorf Conference in September, 1926, by P P. Mühlens (Hamburg) and Prof. F. Sioli (Düsseldorf), name of plasmochin was given, and under this name it issued by the Farbenindustrie Leverkusen, who prepare Bayer Products Ltd. have registered the same product this country under the trade-mark "plasmoquine," a they would like us to point out to our readers that plasmoc and plasmoquine are identical.

An Address
ON
SOME PROBLEMS IN THE ÆTIOLOGY OF
CARDIAC FAILURE.

Delivered before the Inter-State Post-Graduate Medical Association at Kansas City, U.S.A., on Oct. 17th, 1927,

BY SIR JOHN F. H. BROADBENT, BART., M.D. OXF., F.R.C.P. LOND.,
PHYSICIAN TO ST. MARY'S HOSPITAL.

HEART failure has been defined as the inability of the heart to discharge efficiently its function of circulating the blood, and the essential cause of heart failure is stated to be some damage to the heart muscle which impairs its efficiency as the propelling and regulating mechanism of the circulation. Though it is true that the functional capacity of the heart depends on the integrity of its musculature, it must also be borne in mind that its efficiency as a pump may be impaired by lesions of the valves and by disorders of rhythm.

In investigating the problems of the ætiology of heart failure all these factors have to be taken into consideration and their relative importance carefully weighed. We must also have in our minds some criterion as to what constitutes heart failure, what are the early symptoms of its onset, what agents are likely to bring it about, and whether it is likely to be a temporary or permanent condition.

All these points are important from the point of view of prognosis, and in heart disease the question of prognosis is of the utmost importance both to physician and patient. The latter will want to know the degree of seriousness of the heart affection, whether he is in danger of sudden death, and what are his prospects in regard to the future; the former will have to decide these points, state what amount of exercise can be taken with safety, and instruct his patient how he should regulate his life to his best possible advantage.

In deciding these important points many factors have to be taken into consideration—first of all, whether the patient has actual heart disease, or whether the symptoms he attributes to heart disease are due to other causes. If they are attributable to some affection of the heart, the physician must decide whether this is a temporary condition, the result of some recent acute illness or toxæmia, or loss of tone from overwork or neurasthenia; or, on the other hand, to organic disease of the heart, either of the valves or myocardium.

Speaking generally, we may classify affections of the heart in three main groups—diseases of the valves, of the myocardium, and disorders of rhythm—but no hard-and-fast line can be drawn, and the condition of the myocardium must always be taken into consideration, since it is the dominating factor in the functional efficiency of the heart. Taking these seriatim, I will deal with valvular disease first, and endeavour to show what part it may play in contributing to heart failure.

VALVULAR DISEASE.

As the result of the establishment of a valvular lesion of any degree of severity, certain changes take place in the walls and cavities of the heart, which represent an attempt on the part of Nature to counteract or compensate for the ill-effects of the lesion. These changes consist of hypertrophy of the walls of one or other of the ventricles, together with dilatation of some of the cavities of the heart, but however efficiently they are carried out as a counteracting measure, the mechanism of the heart as a pump must be seriously impaired and the hydraulics of the circulation in some degree upset.

For instance, in mitral stenosis we have a nozzle gradually decreasing in circumference as time goes on, damming back the circulation in the lungs, and incidentally giving rise to dilatation of the left auricle, with the result that an increasing amount of work is put on the right ventricle, which hypertrophies at first in response, but in the long run gives way under the prolonged and increasing strain. In aortic incompetence the left ventricle dilates and subsequently hypertrophies as a result of the reflux from the aorta, and carries on for a time, but even tually tends to give out from the prolonged effort under a serious mechanical disadvantage. The vascular system also adapts itself to meet the altered requirements of the circulation. Thus in mitral or aortic stenosis we find the vessels, taking the radial artery as an example, contracted down and smaller in calibre in proportion to the degree of stenosis, to adapt themselves to the diminished volume of blood propelled through the narrowed orifice. In aortic incompetence, on the other hand, when we have a dilated and hypertrophied left ventricle pumping an abnormal quantity of blood with increased force into the circulation, we find the arteries enlarged to accommodate the increased volume of blood, and the arterial system relaxed by vasomotor dilatation, so that the peripheral resistance is diminished and the work of the heart proportionately lessened.

From the degree in which these various changes manifest themselves, it is possible to form a fairly accurate estimate of the extent of the valvular lesion, and from the readiness with which symptoms of cardiac distress are induced by exertion one is able to judge as to the efficiency of these changes in compensating for the lesion. It is obvious that a valvular lesion when severe may be an important contributory factor to heart failure.

AFFECTIONS OF THE MYOCARDIUM.

Valvular lesions impair the mechanism of the heart as a pump, but the functional capacity and driving power of the heart, which is the more important consideration, is dependent on the integrity and soundness of the muscular walls, and though it is a comparatively easy matter to estimate the degree of severity of a valvular lesion, it is often very difficult to decide, with any degree of accuracy, as to the extent and nature of the damage in affections of the myocardium.

When essaying the latter task, we must bear in mind what are the essential characteristics of cardiac muscle. These were originally defined by Gaskell as: 1. Contractility. 2. Tonicity. 3. Conductivity. 4. Excitability—i.e., the power of responding to a stimulus, as a result of which contraction takes place. (In this connexion heart muscle has two peculiar properties: when stimulated it contracts to the full extent of its capacity; after contraction there is a refractory period during which it is incapable of responding to a further stimulus till a certain degree of energy has accumulated during diastole.) 5. Stimulus production, or the power of originating a rhythmical stimulus in response to which the heart contracts.

The last three properties are more particularly concerned in disorders of rhythm. The first two, contractility and tonicity, have more especially to be considered in discussing questions as to the functional capacity of the heart and the causes of heart failure. The efficient working of the heart is dependent on the integrity of these two important properties of the heart muscle, and damage to the myocardium may impair one or both of the functions with which they are concerned.

Before we discuss the causes of the impairment of the functional capacity of the heart, and of dilatation in particular, it is necessary to clear the ground by considering what are the effects of severe exertion on a healthy heart. In the well-trained athlete the heart responds to exertion by increased output and increased rate of beat. To supply the increased output it is possible that there is some physiological

increase in the capacity of the cavities of the heart during diastole, so that they accommodate an increased amount of blood. But the heart contracts more strongly, and, what is most important, completely empties itself of blood at each systole. In a short time after the cessation of exertion the pulse-rate settles down to normal. In the unfit or unhealthy individual, when the reserve power of the heart has been diminished by disease or other causes, undue exertion may lead to dilatation, with incomplete emptying of residual blood, and a very rapid pulse-rate which does not readily subside.

In the healthy young adult all the evidence tends to prove that the normal heart does not become dilated, however much its working capacity is taxed by exertion. This is borne out not only by the experience of athletes but by experimental evidence. Some years ago Dr. Balint Rezsoe,[1] of Budapest, carried out a series of experiments to demonstrate this. Healthy young porters were made to wrestle up to exhaustion, with absolutely negative results as regards dilatation. A dog was made to rotate a wheel until completely exhausted, till it finally dropped, but no increase in the size of the heart could be detected. A large number of patients were requested to do certain work up to the limits of their endurance, but no appreciable dilatation occurred. In all these experiments the results were confirmed by accurate measurement of the size of the heart before and after exertion by means of X rays.

The reserve power and functional efficiency of the healthy heart in the young adult thus appear to be almost unlimited. We have now to consider what are the causes which will impair this efficiency. First, I will refer to those which impair the tonicity of the heart muscle and thus bring about dilatation.

Tonicity.

Tonicity is the property which maintains the heart muscle in a state of "tone" or static contraction, so that it does not completely relax during diastole and allow the ventricle to become over-distended, and also keeps it, so to speak, tuned up, so that it is ready at once to contract effectively when the stimulus reaches it. Impairment of this function of tonicity is the main ætiological factor in dilatation of the heart. Dilatation implies the giving way of the walls of the heart, and ventricular dilatation, or the giving way and stretching of the wall of the ventricle is an important ætiological factor in heart failure in a large group of cases. In other words, heart muscle that has lost its tone may be compared to india-rubber or elastic which has more or less perished, so that it is less resilient and gives way under the pressure of the contained blood.

Causes of Impairment of Tonicity.

Bacterial toxins of all kinds impair to a varying degree the tonicity of the heart muscle, notably those of influenza, pneumonia, and typhoid fever, but the most deadly toxin is that met with in the rheumatic heart affections of children, and in rheumatic pericarditis I think all will agree we may see the most extreme degree of cardiac dilatation. The recuperative power of the heart in the young in such cases when failure results from dilatation is very remarkable, as instanced by the wonderful recoveries one sees from rheumatic pericarditis where the dilatation has been extreme. On the other hand, when the dilatation persists, the more especially if the pericardium becomes adherent, we have a fruitful cause of heart failure. The left ventricle hypertrophies to deal with the increased volume of blood it has to propel and with the hampering effects of the adhesions when they are present, and we have a greatly enlarged heart, with mitral incompetence probably present in addition as a result of the dilatation, struggling against almost insuperable obstacles, and however plucky the struggle, it cannot be many years before it breaks down.

[1] Orvosi Havi Ertesito, vol. vii., No. 5.

In Graves's disease there is often marked dilatation of the heart. The cause of this is not altogether clear. The rapid action of the heart must tend to exhaust the cardiac muscle and this may be a contributory cause, but the cardiac dilatation is associated with marked loss of tone of the arterial system, as well as of the myocardium, for both of which it would appear that the excessive thyroid secretion must be responsible. The dilatation may be very great and subside with the recovery from the Graves's disease. I have notes of a case of a lady of 40 suffering from this affection, with great cardiac dilatation, the apex-beat being in the sixth space almost in the anterior axillary line with a loud blowing systolic murmur, and some œdema of the legs. On recovery from the Graves's disease some years later the mitral murmur had disappeared, the apex-beat had come in to the nipple line, and the heart had regained its normal size.

Chronic alcoholism may in course of time be responsible for cardiac dilatation with some degree of mitral incompetence from its deleterious effects on the heart muscle. Various debilitating influences, such as prolonged nervous strain, unhealthy surroundings, poor nutrition, neurasthenia, and over-work may impair the tonicity of the heart muscle and lead to some degree of dilatation. Degenerative disease of the myocardium, fibrosis, and fatty degeneration, the former often the result of cicatricial changes following severe rheumatic carditis, may be a cause of dilatation and heart failure. Syphilis also may damage the vessels or myocardium. In later life we come across some cases of heart failure associated with great dilatation in which no definite cause can be traced for the dilatation or breakdown except perhaps wear and tear.

Diagnosis of Dilatation.

The presence of dilatation may be ascertained by percussion in the majority of cases, especially in the young, but it is not always an easy matter to percuss out the exact outline of an organ situated behind a bony framework and overlapped to a varying degree by lung, and in adults with excess of adipose tissue particularly women, or when emphysematous lung overlapping the heart practically obliterates the dullness, it may be impossible. In such cases the X ray picture may be of great service.

Other indications of dilatation may be: 1. Displacement of the apex-beat with a diffuse and slapping impulse. 2. Alteration in the character of the first sound which tends to lose its low pitch and become short and snappy. 3. The development of a mitral systolic murmur. 4. Acceleration of the pulse-rate.

Impairment of Function.

As has already been stated, a healthy heart contracts strongly with limited diastolic distension, and practically empties itself at each systole. It responds to exertion by increased output and increased rate of beat, and continues to empty itself at each systole. The conditions are materially altered when dilatation is present.

Starling[2] put forward the following explanation of heart failure resulting from impairment of tonicity:—

"When the heart is dilated and its tonicity impaired the diastolic distension may be excessive, and the heart does not completely empty itself at each systole so that there is some residual blood. In response to exertion, it might be expected that there would be some increase in output as a result of the increased capacity of the ventricle and the increased effort made by the heart, but the main result is increase in the residual blood and not in the output. An attempt is made by increase in the rate of beat to supply the increased output called for by exertion. This may to a certain extent suffice for a time, but eventually the heart muscle gives out as a result of working at an excessive speed, and the output becomes insufficient for the needs of the body."

Contractility.

I stated that the efficient working of the heart is dependent on the integrity of its properties of tonicity

[2] Prof. E. H. Starling: THE LANCET, 1921, ii., 1199.

and contractility. I have dealt with tonicity, and we have now to consider how impairment of contractility can be recognised and what are its results. This is not altogether an easy problem. The chief symptom of failure of contractility would appear to be præcordial pain on exertion, and a risk of sudden death, in the absence of any very characteristic physical signs; in other words, the clinical syndrome of what is known as angina pectoris. In support of this Mackenzie[3] states:—

"I have taken a number of tracings from patients who have suffered from angina pectoris during attacks and when free from pain, and analysis of these tracings enables me to say that angina pectoris can occur when the excitability, conductivity, and stimulus-production are unimpaired. There remain the function of tonicity and contractility. The evidence of failure of tonicity is mainly shown by dilatation, and typical attacks of angina may occur when the heart is normal in size. Thus angina may occur when there is no impairment of tonicity."

The logical conclusion is, therefore, that the anginal syndrome is indicative of failure of contractility. Further positive evidence is, Mackenzie states, the fact that angina is sometimes associated with pulsus alternans which he regards as the characteristic sign of depressed contractility. Though criticisms may be brought against it, this conception of failure of contractility is a very helpful and rational one. The præcordial pain which occurs on exertion in angina is a sensory reflex and may be regarded as a warning sent out by the heart that the limit of its reserve has been reached, and that it is unable to cope with the increased demand on its energy entailed by the additional exertion.

It does not fall within the scope of this paper, nor would time allow me to discuss the character of the pain in angina, or the explanation of its distribution according to Head's hypothesis or even the differential diagnosis of præcordial pain. I am aware that there is some controversy as to the origin of the pain and the cause of death in angina, and that Clifford Allbutt put forward the theory that disease of the aorta was responsible for the former, and vagus inhibition from the shock of the severe pain for the latter. It seems, however, incredible that mere pain should cause arrest of the heart's action, unless the myocardium had been damaged and its functional activity seriously impaired by disease or interference with its blood-supply, and even assuming that disease of the aorta was responsible for the pain, of which there is no proof, there is then no apparent reason why exertion should induce an attack of pain. Moreover, extensive disease of the aorta resulting in aneurysm may occur without giving rise to præcordial pain. Many other theories have been put forward to explain the pain in angina, but I submit that the one I have suggested affords a reasonable and satisfactory working hypothesis.

What, then, are the factors which are responsible for heart failure in angina? It is generally admitted that the grave forms of angina are associated with serious pathological changes in the coronary arteries. Osler held this view, and Huchard, the French heart specialist, stated in his book on heart disease: "There are not several varieties of true angina, there is only one, that associated with disease of the coronary arteries." The most serious effect of disease of the coronary arteries is interference with the blood-supply to the heart muscle from thickening of their walls or narrowing of their lumen, of which the most severe degree is met with in syphilitic endarteritis obliterans, or from obstruction of their orifice by syphilitic disease of the aorta.

One can readily understand how the heart, dependent for its very life and ability to function on a free supply of blood through the coronary arteries, may when it is starved of blood by narrowing of their lumen, send up a cry of despair, when called upon for increased effort to which it cannot respond without an increased blood-supply. If the exertion is too severe or is persisted in, the heart comes to a standstill. Analogous to this is the "claudication intermittante" of French authors, first described by Boullay in 1831, sometimes met with in old horses with degenerated thickened vessels through which an adequate supply of blood does not reach the muscles in the legs. When called upon for too severe or too prolonged effort the muscles cannot respond and the animal comes to a standstill.

Narrowing of the lumen of the coronary arteries by endarteritis or obstruction of their orifice by syphilitic aortitis will cause the most severe and grave interference with the blood-supply to the heart muscle, and in less degree thickening of their walls or of the intima from arterio-sclerosis or atheroma and degenerative change will have the same effect. One or other of these changes is commonly found at autopsies on cases of angina pectoris. Many instances, however, occur in which no obvious disease of the coronary arteries is found post mortem in patients who have had during life symptoms indistinguishable from the anginal syndrome—that is, who have suffered from severe præcordial radiating pain on exertion, and have died suddenly. One also frequently meets with cases in which præcordial pain on exertion is a prominent symptom, but who make a good recovery and lose their symptoms. How can we reconcile this with the statements made by Huchard and others that true angina does not occur in the absence of coronary sclerosis?

We must first of all disabuse our minds of the idea that angina pectoris so-called is a disease. The term itself is derived from the Greek word ἀγχόνη, which means literally a strangling or throttling, hence we have the Latin word angina and the English agony. In medical parlance the term angina is employed to denote a syndrome of symptoms, the chief of which is præcordial pain on exertion, which are met with as a result of impairment of function of the heart muscle due to pathological changes. I have already stated that it is impairment of the property of contractility of the heart muscle which appears to be responsible. Contractility is the most vital and essential property which enables the heart to fulfil its function of propelling the blood into the circulation. Obviously if it fails completely, even for a moment, the heart must come to a standstill. The most serious pathological lesions, entailing grave and permanent impairment of contractility, are lesions of the coronary arteries or their orifices interfering with the blood-supply to the heart muscle, and of these syphilitic lesions are the most fatal. It is quite intelligible, however, that causes other than the cutting off of the blood-supply may impair contractility, for instance, fatty or fibroid degeneration of the heart muscle, which when advanced may prove almost as serious, and cases of sudden death are not uncommon with these conditions. On the other hand, there may be minor degrees of impairment of contractility associated with præcordial pain on exertion, due to depressing conditions of a temporary nature from which recovery is possible.

Disorders of Rhythm.

There remains for consideration the part played by disorders of rhythm in precipitating a cardiac breakdown. These may be classified as follows: 1. Impairment of conductivity leading to heart-block of varying degree, exemplified in its most severe form in the Stokes-Adams syndrome. 2. Acceleration of heart-beat, as in auricular flutter and paroxysmal tachycardia. 3. Irregularity in force and frequency of rhythm. (*a*) Sinus arrhythmia; (*b*) extrasystoles; (*c*) auricular fibrillation.

I do not propose to discuss the ætiology of, or the explanations put forward to explain, these various phenomena, but simply refer to the bearing they have on heart failure.

Heart-block.—Minor degrees of heart-block due to a temporary depression of conductivity which may result after some acute infection are not, as a rule, of any serious significance. In the more severe degrees

[3] Sir James Mackenzie: Diseases of the Heart, first edition, p. 40.

of heart-block, due to compression of the conducting fibres in the bundle of His by inflammatory exudate or cicatricial tissue, the prognosis is more serious, for though patients may survive many years with a very low pulse-rate, they are liable to syncopal attacks or some other manifestation of the Stokes-Adams syndrome induced by temporary cerebral anæmia, which may prove fatal.

In *auricular flutter and paroxysmal tachycardia* the attacks are, as a rule, of limited duration, but if very prolonged or very frequent they may exhaust the contractility of the heart muscle and lead to a fatal issue. Sinus arrhythmia and extrasystoles call for no comment, as they are of no serious import in themselves.

Auricular fibrillation occurring in the later stages of valvular disease, more especially in association with mitral stenosis, is stated by some authors to be the determining factor in the final breakdown of the heart. Doubtless it is a serious additional handicap to a heart already labouring under the mechanical disadvantages imposed by the valvular lesion and the changes in its walls and cavities entailed thereby. In the absence of a valvular lesion, however, auricular fibrillation may persist for many years in certain individuals without giving rise to any serious symptoms or even inconvenience. I have watched four cases of this nature for 15 to 20 years, and have been astonished to see how little the patients were incommoded; though electrocardiograms showed typical fibrillation in the two cases, I had the opportunity of obtaining them. Disorders of rhythm are of great interest, and may cause considerable discomfort to the patient, but they do not, I think, in the majority of cases play a predominant part in bringing about heart failure, though in some they may contribute to it.

In conclusion, let me say that in this communication it has been my object to outline a clinical scheme for the investigation of heart failure. When confronted with a case it is not sufficient to make a diagnosis of valvular disease or cardiac dilatation, &c., but we must make some definite idea as to the relative importance of the factors which may contribute to a cardiac breakdown, and as to the part played by any one of them in bringing it about. It is only thus that we can have a satisfactory basis for prognosis, and for formulating an adequate and suitable line of treatment.

A STUDY OF THE INCIDENCE OF THE MINOR PSYCHOSES:

THEIR CLINICAL AND INDUSTRIAL IMPORTANCE.*

By MILLAIS CULPIN, M.D. Lond., F.R.C.S. Eng.,
LECTURER ON PSYCHONEUROSIS TO THE LONDON HOSPITAL MEDICAL COLLEGE.

THIS work arose from an inquiry into telegraphists' cramp, undertaken by the Industrial Fatigue Research Board, who, assuming cramp to be a fatigue phenomenon, detailed two of their investigators, Miss May Smith and Mr. Eric Farmer, to conduct the inquiry. These workers found that cramp showed none of the characteristics of fatigue, but presented a medley of symptoms, of which many seemed to rest upon a psychological rather than a physiological basis. I was then given the opportunity of interviewing cramp subjects and a control group of non-cramps in order to find out whether cramp was associated with other symptoms of a recognisably psychoneurotic type. This was found generally to be the case, the other symptoms being often of a degree which would lead to the diagnosis of a severe psychoneurotic state apart from the cramp; they had often preceded by years the onset of cramp.

This result was not unexpected; but it was disconcerting to find that the controls also showed a considerable, though smaller, proportion of men and women suffering from similar symptoms. Was this proportion, like cramp, to be attributed to some feature of the work, or was it a phenomenon common to the general population? In other words, what number of the general population suffer from symptoms of a minor psychosis? (Although custom compels me to use the word *psychoneurosis*, yet its metaphysical implications lead me to prefer *psychosis*, with the prefix *minor* as a distinction between these mental disturbances and others typically leading to certification.)

We next examined 100 learners in the school of telegraphy, all of or about the age of 16. Here we found what was, to us, a surprising number of symptoms, often quite severe. One lad, aged 19, produced the following material:—

"I don't get on any too well. I'm under the impression something is wrong, and that makes it go wrong. I have trouble with V and 4; I want to rush them." Worse when watched. Has feeling of being observed, but "has hardened himself." But cannot buy his own clothes; gets his brother to buy them. Has *sentiment incomplétude*. "I always imagine what would happen in an accident." Has few friends. Has political opinions, but is always trying to convince himself. Few sports; fond of walking alone.

Fifty-four of the group passed my scrutiny as being free from symptoms, 27 showed slight symptoms, whilst in 19 they were classed as severe. This pointed to the conclusion that predisposition played a great part in the development of cramp, and indicated the presence of an unsuspected number of people who, even in youth, could be identified as likely to fall victims to disabling symptoms if placed in circumstances that might stimulate the latent psychosis.

Further to the psychological examination, each subject was tested by means of the McDougall-Schuster dotting machine, the pursuit-meter, and by the piezograph, an instrument devised to record the pressure exercised in using the morse key. The results of these tests showed some correlation with those of the examinations, but the dotting test was finally adopted as an objective check upon the results of the psychological investigation.

The results of the research up to this point are published by H.M. Stationery Office under the title of "A Study of Telegraphists' Cramp." Only a part of them will be dealt with in this paper.

Time Lost through the Minor Psychoses.

It had become clear that disabilities arising from the minor psychoses played a great part in swelling the totals of time lost through illness, whether diagnosed as neurasthenia, nervous breakdown and such like, or under the guise of gastritis, cardiac debility, dysmenorrhœa, or other manifestations of what are properly called neuroses. We now obtained sickness records from various Government departments and private firms, which showed extraordinary diversity between one and another, not only in the gross amount of illness, but in its nature, as indicated by the diagnostic classifications.

TABLE I.—*Establishment F. C.*

Days lost.	Diagnosis.	Days lost.	Diagnosis.
48..	Cold abscess of thigh.	72..	Appendicitis; operation.
48..	Duodenal ulcer; operation	38..	Motor accident.
33..	Appendicitis: operation.	90..	Pulmonary tuberculosis.
126..	Injured in motor accident	108	,, ,,
42..	Influenza.	98..	Renal calculus; operation
30..	,,	222..	Sarcoma of ilium.

Average days sick leave per head per annum is 3·6.

Establishment W. H.

Days lost.	Diagnosis.	Days lost.	Diagnosis.
156..	Influenza and pleurisy.	109..	Cardiac and nervous overstrain.
159..	(In separate periods.) Influenza, influenzal debility, nervous debility, nervous exhaustion, influenza.	92..	(In two periods.) Debility after appendicitis, influenza, lumbago.
124..	Nervous debility.	140..	Rhinitis.
181..	Cough, high blood pressure, bronchial catarrh, and fibrositis.	243..	(In two periods. Pyrexia, hydronephrosis
278..	Dyspepsia and nervous debility.	105..	General debility.
		94..	Debility.
		123..	Nervous breakdown.

Average days sick leave per head per annum: 7·7 for men; 14·1 for women.

[1] A paper read to the Section of Psychiatry of the Royal Society of Medicine.

In Table I. the details are given of cases involving long sick-leave in establishment F. C. for one year and in W. H. for the same period, except that, the latter establishment being the larger, only the first 12 cases are taken.

Establishment B. N. provides a contrast between different years (only selected diagnoses are given; the figures refer to total days lost):—

TABLE II.—*Establishment B. N.*

	1923.	1924.	1925.
Anæmia	257	386½	418
Gastric	476	624	890
Dysmenorrhœa	197½	174	177½
Neurasthenia, nerves, and general debility	1705½	1206	1070½

Average staff is about 960, and 85 per cent. are females.
Days lost per annum: 7·2.

After 1923 the medical staff paid attention to the prevalence of the "neurasthenia" sick-leave, with the result that it diminished, as is shown; but the increase under the heads of "anæmia" and "gastric" left the total practically unaltered.

The local incidence of dysmenorrhœa varies strangely. One large firm, with excellent welfare arrangements and their own medical staff, has a high sickness-rate; in the year 1924 it was 14·41 and 16·48 days per annum for females in the age-groups 18 to 22 and over 22, and of the total days lost by the female staff 14·9 per cent. were due to dysmenorrhœa. Another large firm, a store employing about 1500 hands, has a maximum sick-rate of 2·6 days per annum, and by adding in the time spent resting in their sick-room the proportion from dysmenorrhœa reaches from ½ per cent. to 1 per cent. For purposes of comparison this figure should be doubled, as only half the staff are females. The firms are reasonably comparable with regard to material conditions.

Method of Investigation.

These figures indicate a serious interference with health and efficiency, and Miss Smith and the writer were now enabled to widen their investigations in an effort to ascertain some of the factors concerned in them. Questions calling for answer seemed to be: (1) What proportion of the population suffer from minor psychoses? (2) Do such people tend to enter particular occupations? (3) How far does occupation determine the outbreak of symptoms? The work already done showed that it is possible in an interview of about 20 minutes to find out with reasonable certainty the presence of typical symptoms in subjects who submit themselves voluntarily to such inquiry. With the exception of a few subjects showing, in the presence of symptoms, that mental attitude described by Charcot as "la belle indifférence de l'hystérique," and others—perhaps less than 1 per cent. of the total—who appeared to be on guard against revealing their weaknesses, the subjects gave every assistance. It is still to me a cause of amazement that some of them should pour out to a total stranger a mass of emotionally charged symptoms which have never been previously confessed. Indeed, I was often thanked for listening to them.

My leading questions have settled down into a regular form; it must be borne in mind that offence had to be strictly avoided; a single complaint might have wrecked the inquiry in the particular establishment where it occurred, but apparently harmless questions proved sometimes very searching. "Do you look forward to sticking to this job till you draw your pension at 65?" has one effect when put to a bright young thing of 19, and one quite different when asked of a woman of 35. A question originally used as a conversational gambit, "How do you like the work?" furnished answers that we think will have a statistical correlation with neurotic illness and soon gave us an insight into the state of harmony between the workers and their chiefs. Moreover, when a reasonable harmony existed in an establishment the question often revealed at once the mal-adjusted psychoneurotic.

But the search for symptoms was the chief aim. Anyone unfamiliar with the work might be puzzled if invited to ascertain whether a person is what is popularly called "neurotic," but the simplest method has proved to be direct inquiry. "Do you call yourself a nervous person?" generally brings forth an honest answer, and the subject may at once plunge into an account of his symptoms. If not, I ask first about fear of the dark, whether it existed in childhood, what form it takes, and whether it interferes with behaviour. Uncomfortable sensations of being observed come next; a surprising number of people of both sexes and of all classes declare they are too sensitive to go alone into a restaurant. Inquiry into the *sentiment d'incomplétude* is often the key that unlocks a host of obsessional symptoms. "Does anything in particular make you nervous?" opens up the way to the phobias, though specific forms may be sought. Sports and amusements pick out the socially adjusted, questions about dancing bring out the attitude to the opposite sex, and "Could you tell a lie with a cheerful countenance?" is not a test of morality, but the touchstone for *les scrupuleux* of Janet. Poise and general behaviour are observed, sweating hands and nail-biting are discussed, if noted. The former is often admitted to be a sign of immediate nervousness, and the latter, I have found, often appears long after childhood, at a time of emotional stress, and persists after the period of stress is over.

Some details of general psychological interest came to light, involving day-dreaming, the effect of noise, and the reaction to war experience.

Day-dreams.

Many of our subjects were occupied in routine work, such as entering amounts against names, arranging names under indexes and the like; others were typists, and, of course, we started with telegraphists. A question was framed to elicit how far such workers could divide their attention: "When you are at work do you think of it all the time, or can you let your thoughts go on to other things?" Some unexpected general principles emerged. The well-adjusted worker, as a rule, can carry on whilst his thoughts are elsewhere, even at such work as typing from shorthand notes; but if a difficulty arises, or he makes a mistake, the whole of his attention returns to the work in hand; in such cases the work, as judged by his superiors, is quite satisfactory, and he makes no more than an average number of mistakes. A few of the class without symptoms, generally conforming to Jung's extrovert type, seemed unable to grasp the purport of the question. Whether they never day-dreamed, or whether they lacked enough insight to recognise what they were doing I could never decide; they would sometimes declare that they could not imagine thinking of anything but the immediate work; a woman sewing, for example, would be assumed by such people to think of her sewing and nothing else.

A very different mental attitude is shown by other subjects. One may reply: "Oh, I always have to concentrate on my work or I should make mistakes"; and such an answer is, as events proved, the invariable prelude to the discovery of minor psychotic symptoms either of the anxiety or over-scrupulous type. I have, indeed, come to regard this striving for concentration as itself a psychoneurotic symptom. It is not, as a superficial observer might expect, necessarily correlated with efficient work.

There is a decided reticence, in both sexes, regarding the content of the day-dream. The conditions of the investigation prevented close questioning, but the admission was sometimes obtained that they were "castles in the air" and sometimes a fairy prince came into the story. Exceptional cases occurred in which the subject declared that work was a welcome means of keeping out unpleasant thoughts; this statement opened the way either to an admission of troublesome obsessional thoughts or to the discussion of some serious current stress.

Noise.

Few opportunities were offered of noting the effect of noise, but so far as our studies went, the well-adjusted subject is able to accommodate to noise after a day or two of discomfort; complaints of ill-results from noise came mostly from subjects with definite symptoms. There is a difference between noise made by oneself and that made by others, also between noise that is essentially a part of the work process and noise that is extraneous. Reaction to noise depends upon a mental attitude which regards it as a definite assault upon the subject's right to quiet. Those minor psychotics who have "good days and bad days" naturally suffer more on a bad day, and even some of the healthy class will admit to suffering from noise when they are "out of sorts."

Post-war Cases.

Ten years' experience of the treatment of the minor psychoses following war service has reduced to a commonplace the process of suppression. Every genuine war case—with the exception of a few obsessionals—presents an example of the suppression of emotionally charged war memories, ranging from a mere reluctance to talk about distressing incidents to a gross amnesia. Yet I had an uncomfortable knowledge that control cases had not been investigated, and this work gave me the opportunity of examining men who had passed mentally unscathed through strenuous war experiences. The result is decisive; men with war service who are found free from symptoms, when invited to relate the worst experience they passed through, will after a moment's thought produce such experiences, sometimes with a healthy expression of regret or disgust. Men with well-defined symptoms—whether supposed or not to be suffering from war-strain—display the usual resistances that show themselves in patients under treatment; they claim to have forgotten, or express annoyance at being asked to revive past horrors, or give generalised accounts with no personal or emotional value. The difference between members of the two groups is pathognomonic.

Standards of Assessment.

An early difficulty was the setting up of standards which would be stable and as far as possible independent of personal judgment. There have admittedly been variations in our standards, or, rather, standards have become better defined as the work progressed. At first I divided the subjects into those with and those without symptoms, the symptoms being divided into mild and severe. This was found inadequate, and six assessments were decided upon, ranging from 0 to +5; the standard of the last assessment was that I judged the subject to be in serious need of treatment on account of interference with happiness or efficiency, or both. I also noted, when possible, whether the predominating symptoms were those of hysteria, anxiety, or of an obsessional state. For the moment I only claim descriptive utility for these qualifications.

The presence of an apparently unimportant symptom—nail-biting, for example, or fear of the dark—did not at first exclude a subject from the 0 class, but cases occurred in which a symptom of that nature proved to be, as it were, at the peak of a symptom complex that almost escaped detection; hence any symptom whatever now places the subject at least in the +1 class. Whether that is justified may be debated, and for present purposes the 0 class and the +1 class may be added together for purposes of comparison between different groups. We regret that inexperience allowed us to be satisfied with a less detailed classification in our original Post Office work.

The placing of subjects in the other groups cannot be reduced to a system; it depends upon a weighing-up of all the symptoms and such impressions as are received during the interview.

Those cases, less than 1 per cent. of the total, in which I suspected that the subject was on the defensive, have been omitted from our figures, but it is significant that they nearly all came very badly through the dotting test. One subject presented such a curious mental picture that I could not decide whether he was an unrecognised genius or a mattoid. Two cases of mild recurrent melancholia—called neurasthenia—were detected and are omitted; also a mentally defective girl earning her living in a laundry, one probable dementia præcox, a woman of 35, who gave me an impression that she was hiding symptoms of a major psychosis, and a man whose case is of sufficient interest to be related now.

A lorry driver, aged 20. (Asked about day-dreams)—Sometimes has horrible thoughts; "fed up" with himself; suicidal thoughts. (Asked about feeling of being observed)—"Everybody's looking at me; sometimes I glance back and see them talking." (Do you worry about what others think of you?)—"They talk of me behind my back." "Mother is an invalid—in terrible agony; her illness started like mine—she told me so. Hers was hurried on through hard work, and the foreman says I'm not strong enough for the job. I get pains in my stomach and go dozy and sleepy." Admits he has had two or three mishaps when driving. Wears glasses for headache (+1·5 cyl.). Dotting score, 130.

This patient should be compared with another lorry driver, aged 25, in the same employment. He has never had a mishap in seven to eight years of driving. Has no symptoms whatever, but was operated upon for squint. Wears +2·25 cylinder in front of his good eye and, to rough tests, has no stereoscopic vision. Dotting score: 216.

The Dotting Test.

The McDougall-Schuster dotting machine consists of a revolving disc—like a gramophone disc—on which is fixed a paper bearing a spiral of small circles, at each of which the subject is instructed to aim with a stylograph, as they come into view through a slot in the cover. Since the spiral begins near the centre of the disc, it follows that the dots pass more and more rapidly in and out of view, and at last their speed is so great that few people succeed in hitting more than a small proportion in the last few sectors. What particular qualities are tested by the machine need not concern us now; the immediate interest is in the fact that Miss May Smith, working independently with it, obtains results that show a definite relation, in every group tested, with the results of my own personal interviews. Each group must be taken by itself, for in such a test workers with a flat-iron cannot be judged by the same standards as workers with a pen; in fact, their results are consistently lower. But in every occupation group those with a high assessment put up on the average a worse performance than the "noughts" and "plus ones." It is only an average, however. We do not claim that in individual cases it has any diagnostic value, except in a small group to be discussed later; but it confirms the significance of my own findings.

Miss Smith analyses the results in various ways, but for comparison I shall consider only the number of hits before breaking-point is reached—that is, before the subject misses as many as five dots in immediate succession.

Correlation of the Dotting Test with Psychological Findings.

Table III. shows dotting results grouped into four classes of descending merit, with a cross classification according to the presence of symptoms. The subjects were learners in the school of telegraphy; those with severe symptoms obtained no first places, 26 per cent. of them being placed in the lowest class. (It is noteworthy that 4·9 per cent. of cramp subjects reach the A class in dotting, thus showing the anomalous nature of the disorder).

The next table (IV.) shows the same and other groups with the mean of the number of hits. The figures headed "V" show the variability within each group, which increases with the severity of the symptoms, except in the case of the non-cramp controls; this indicates that among the severe cases, although the mean is low, yet some members of the group put

up very good records. It will be seen later that a very important reason is offered for this phenomenon, but the absence of variability in the non-cramp controls needs explanation. I believe it is due to my inexperience. They were my first essay in this investigation, and I believe that I missed symptoms which I should now expect to find; so that some of the good performers in the 0 class should be in the other.

Meanwhile, without spending time upon more figures, I will ask you to accept the statement that the correlation between the results of the two methods of examination is constant in all the groups examined.

TABLE III.

Psychoneurotic symptoms.		Dotting. A	B	C	D
None (54)	Number	5	19	26	4
	Per cent.	9	35	48	7
Slight (27)	Number	4	14	5	4
	Per cent.	15	52	18	15
Severe (19)	Number	0	7	7	5
	Per cent.	—	37	37	26

Types Recognised at the Personal Interview.

A pure conversion hysteria was rarely met, though some cramp cases seemed to conform to that type. A hysterical stigma that I frequently "suggested" in my work with war cases is the yielding grip shown when the subject is invited to resist the attempt to pull open the fingers of his clenched hand. This was often seen in cramp cases and I have seen it in three other subjects of this inquiry, always associated with further symptoms of hysteria. Here is one example:—

Female, clerical worker, aged 32. Suffers from rheumatism and headaches. Used to be nervous till the age of 19; had fear of the dark and terrifying dreams. Appendicectomy at 27 after 18 months' pain. Periods ceased for 11 months, then became excessive till hysterectomy was done for fibroids. She gave up nursing because her heart was wrong. Often has heart attacks at work. One lung is also wrong. Wears glasses for headaches. Yielding grip with either hand.

The characteristics of this case are total absence of anxiety in the presence of anomalous physical complaints, and the pathognomonic sign of the yielding grip.

The following is an example of what I call anxiety with hysteria:—

Female, clerk, aged 33. Dislikes the work. Can day-dream without interference with her work. A month ago was away for "nerves." Had made a mistake and it worried her. Always had fear of the dark or of being alone. Nervous if spoken to by strangers. Cinemas try her eyes. Has good and bad days. No energy; improves as the day goes on; has a feeling of "something awful going to happen—a cloud." Tennis is too much for her; influenza left her heart weak. (Asked how that showed itself.) Goes faint in trains and crowds. Could not sit in a small room like this; would make her come over all faint; no, not frightened at all; it's the heart. Wears glasses (+0·25 cylinders) to avoid strain and headache. Had all her teeth out for gastritis before age of 21. Hands are blue. Does not look forward to staying on for her pension. Talks frankly about shortage of men, but declares indifference. Grip good. Assessed at +5. Dotting score, 162.

I do not attempt to define hysteria, but in this case there are frank anxiety symptoms and the readiness of the patient to ascribe her troubles to heart, teeth, and eyes, influences me in adding the diagnostic qualification of hysteria.

The next case is similar clinically:—

Laundry worker, female, aged 34, married, four children. Likes the work very much. Would not change it if given the chance. "My nerves are all bad. The least worry makes me go all of a shake. I worry at the least thing. I'm afraid in the dark or of being alone. Wouldn't go along a dark road." Describes claustrophobia. "Should worry and fidget in this room. Never go in a 'bus; wouldn't go alone in a train; feeling of being observed; never go out by myself." She has to find a companion to accompany her to work. A summons to see her manager would make her go all hot. "All of us have been born with nervous debility." Never goes to the pictures. Is asocial. She has a yielding grip, which she ascribes to rheumatism. Assessed at +4. Dotting, 87.

The interest of this case is in the fact that a woman with these symptoms is able to carry on as a laundry hand without being affected in her work, and without any excess of sick-leave. She looked fairly placid, was rather fat and flabby, and gave no external indication of her minor psychosis.

The next case is one of pure anxiety in a good type of man successfully holding a responsible position.

TABLE IV.—*Dotting Records and Mental Type.*

Psychoneurotic symptoms.	100 learners. Mean.	V.	100 clerical workers. Mean.	V.	Telegraphists: 46 non-cramp subjects and 41 cramp subjects. Mean.	V.
None	171 ± 3·7	24·4 ± 1·64	183·6 ± 3·68	21·9 ± 1·49	176 ± 5·31	23·7
Slight	170 ± 6·1	27·9 ± 2·71	183·0 ± 5·8	21·1 ± 2·34	—	—
Severe	145 ± 7·2	30·6 ± 3·8	170·6 ± 5·5	24·7 ± 2·39	148 ± 5·8	22·6
(Cramp subjects)	—	—	—	—	101 ± 6·8	64 ± 6·48

Aged 37. Likes his work. Would not do work at which divided attention is possible. (This attitude, judged in the light of his symptoms, may represent a desire to keep busy in order to drive away his anxiety.) Is highly strung. Wakes up and thinks of his work. Tended to stammer after the war. Speaks slowly now as a result. Was afraid of the dark after the war. Hates social activity: dances and such-like. Gets frightened at a tea-table. Has now got over the inordinate dread he had after the war. Describes claustrophobia. Hates theatres. Is able to lecture in spite of his fears. Hopes he could tell a lie if he wanted (absence of obsessional over-scrupulousness). Has experienced the *sentiment d'incomplétude*, but can "let it rip." Questioned about his worst war experience, he says it is hard to say what it was, then makes a joke about blood and entrails with no emotion whatever. Assessed at +3. Dotting score, 62 (a very bad record).

This man is kept from a breakdown by his keen interest in his work; if some added stress led to a breakdown, it would be regarded as a bolt from the blue if his previous condition was not ascertained.

The Obsessional Subject as Revealed by the Dotting Test.

The correlation between the two methods of examination was occasionally disturbed by a subject with a high assessment doing an exceptionally good performance at the dotting. One day my colleague put before me my notes on half a dozen cases and asked what was common to them all; I answered that they were all "obsessionals" and was told that these were the people who blurred our statistics by their excellent dotting. Here is an example:—

Male, aged 43, doing responsible clerical work. Work is a bit monotonous. Can day-dream without interference with work. Can cast up a column and talk. Writes music and harmonises for fun. Gets a physical sensation from music, but analyses and criticises. (Are you nervous?) "That's a funny question. I get agitated at music or chess." Prefers the dark. Easily gets fidgety and impatient. Strong *sentiment d'incomplétude* since boyhood. Tells a story of a fear that made him always rush past a lavatory. Has a dread of fire. Had to give up chess because of an obsession to arrange everyone in the street in accordance with the knight's or bishop's move. Assessed at +3. Dotting, 322. The best we have seen.

Note the almost entire absence of anxiety as contrasted to the case previously described; note also

the difference in the dotting score in two men, both of whom are well educated and efficient at their tasks. This latter case admittedly shows few symptoms—they are curiosities rather than disabilities—but enough to place him in his group and account for the extraordinary dotting.

The next subject is more likely to come to disaster through her symptoms, which are, I think, ominous in one of her age.

Female, aged 19½, art student. Can draw and be read to; if not read to she has to make up stories. Is very nervous. Has terror of fire—no reason for it. Will not sleep high up in a house. Gets up and goes round the house, and whilst doing so argues the pros and cons. Terrified at thunder or loud organ. No fear of dark but of midday blight (i.e., overhead fog); hates the orange colour. Has feeling of being observed, but ascribes it to her height; to counteract the feeling she has "created an atmosphere of being fast." *Sentiment d'incomplétude* every night of late. Hands shook and she had fear of traffic after an operation. (What operation?) "My inside had slipped." "I dissect my actions and then dissect the dissection. A vicious circle till I nearly go mad. I try; and can't stop. This started at the age of 15. I have nonsense dreams of fire and being chased by bulls. I am social or unsocial in moods and think of marriage in moods." Describes hypnagogic hallucinations. Assessed at +4. Dotting, 236.

Here the fears are quite specific, only appearing in special circumstances and therefore not likely to interfere with the dotting; the main symptoms are obsessional.

Since this behaviour of the obsessional subject was noted Miss Smith has written on every exceptionally good record—before I examine the subject—the words "obsessional or normal," and so far every one so noted has been obsessional. But it does not follow that every obsessional makes a good score. The worst score, apart from cramp subjects, was made by a "plus 5" obsessional who was in a state of severe secondary anxiety.

Table V. shows the mean of the dotting performance of three groups:—

TABLE V.

Diagnosis.	No. of cases.	Mean of the dotting test.
O	250	164 ± 2·0
Obsessional	38	201 ± 5·5
Hysteria or anxiety ..	105	142 ± 3·1

The figures after those expressing the mean show the probable error, calculated statistically. The most important observation is that all exceptionally good records are made by obsessional subjects.

Results of Investigation of Different Industrial Groups.

In Table VI. the percentages are based upon the examination of not less than 100 subjects in each group:—

TABLE VI.—*Percentage Distribution of Assessments in Different Groups.*

—	Clerical work.		Routine clerical.		Laundry.	Art school.	Telegraph learners
	A	B	C	D	E	F	G
0	60	46·4	52	49	43	32	54
+1	19	22	20	21	25	26·8	27
+2	18	20	11	17	12	16	13
+3	3	9·3	10	8	15	14·4	5
+4	0	2	6	3	5	9	0
+5	0	0	1	2	0	1·8	1

Group A represents establishment F. C., whose sickness records I detailed early in this paper. Those records showed an absence of psychoneurotic illness, and this is associated with a high percentage of the first two assessments and an absence of any assessments in the last two groups. But this is not the whole of the information available, for we know that special circumstances directed the attention of the medical staff to the importance of studying the temperamental qualities of their employees, and there had been a definite attempt to exclude people judged temperamentally unfit. The results seem to have been the exclusion of hysterics and of some anxiety subjects, but probably a selection of obsessionals, who are by no means to be rejected on grounds of inefficiency. The firm has a high percentage of employees (84 per cent.) who say they are satisfied with their job.

Group B has not been subject to this selection, and only 62 per cent. are satisfied. Their sickness-rates, however, show no excess of psychoneurotic troubles.

Groups C and D are very similar. There is a considerable amount of psychoneurotic illness, and only 58·4 and 64·3 per cent. are satisfied with their jobs.

Group E produced results that surprised us. We knew that psychoneurotic illness was non-existent therein, and we expected to find a totally different incidence of latent minor psychoses. Yet our findings gave results practically identical with those obtained from clerical workers. (The first two assessments should be added together to give a fair comparison; a change in the standard of assessment has increased the +1 class at the expense of the noughts.) Contentment with the work seems to be a characteristic of this laundry—which is managed on enlightened lines—and it was rare to find a worker who could be persuaded to express a wish to change into any other occupation.

Group F gave us an insight into what is described as the artistic temperament. All its members were in fairly comfortable financial circumstances, and all were in an occupation which they had selected in accordance with their own desires. No illness records were kept, but absence was negligible. The high assessments were largely due to the presence of obsessional subjects.

Group G suggests that symptoms are absent or less easily detected in some young people who will probably show symptoms at a later period. It shows, however, that symptoms are present at an early age and can be detected.

Among the laundry workers are a fair number of girls between 14 and 15 years of age. Although symptoms in them are not well defined, yet types can be recognised and the assessments are confirmed by the dotting test.

Early in our work we found there was no significant statistical difference between the results in the two sexes, and therefore no attempt has been made to keep the figures separate.

General Conclusions.

The dotting test keeps a check upon the results of the psychological examination.

There is a high proportion of people in the general population suffering in varying degrees from the minor psychoses. These may not affect sick-rates in some occupations, but in others may be the cause of considerable loss of time through illness.

There is no reason to believe that there is any active selection of particular occupations by psychoneurotic people, except in the case of art students, where the results of the investigation confirm popular belief about the "artistic temperament."

The results suggest that the commonly supposed "causes" of psychoneurotic illness are merely factors in exacerbating a previously existing condition. Yet the fact that such illness is absent in some groups indicates the importance of studying exacerbating factors that must be present in those groups with high sick-rate.

MIDDLESEX HOSPITAL.—The sum of £1000 has been contributed towards the hospital's rebuilding and development fund by Mrs. Bethell "as a token of her great esteem and affection for Sir Rowland and Lady Blades." Sir Rowland Blades was Lord Mayor of London last year.

TUMOURS OF THE SPINAL CORD.

By ALEX. MILLS KENNEDY, M.D. Glasg., M.R.C.P. Lond.,
PROFESSOR OF MEDICINE AND DIRECTOR OF THE MEDICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF;
AND
LAMBERT ROGERS, F.R.C.S. Edin.,
ASSISTANT IN THE SURGICAL UNIT, WELSH NATIONAL SCHOOL OF MEDICINE, CARDIFF.

Spinal cord tumours are perhaps most often recognised in special neurological clinics where all kinds of nerve cases are sent. Hence it is not without interest that all the six cases here recorded appeared in the general wards of this medical unit within the space of one year. The majority, in fact, occurred within a period of a few months. There were five males and one female. Their ages were: males, 16, 27, 50, 51, 54; female, 16. There was no occupational incidence. Only one case (Case 1) dated the onset of his symptoms from an accident—a severe bruise over the great trochanter four years previously. Another (Case 5) slipped and fell while lifting a heavy weight, but this occurred six weeks after he had first noticed symptoms. None of the others had received any injury whatsoever. It must be remembered that at the onset the symptoms may be slight, and any interference with walking may be easily overlooked until, perhaps, one day the patient stumbles at his work, and from this time he becomes aware of some difficulty in walking. If he were doing anything particular at this time—e.g., lifting a heavy weight—he may be led to believe that it was this that caused him to stumble and so was responsible for his present condition.

Four of the cases suffered from "girdle" pain, and in three of these it was associated with an encircling band of cutaneous hyperæsthesia. One of the cases, with no complaint of "girdle" pain, exhibited an encircling band of cutaneous hyperæsthesia, and only one case (Case 2) had neither "girdle" pain nor hyperæsthetic band.

The earliest symptoms were usually weakness or heaviness and stiffness in the legs—usually one leg first—and consequent difficulty in walking. One patient, however (Case 2), had complained of "neuritis" (pain) in feet and legs for nine and a half years before the onset of weakness in the leg. Another (Case 3) complained of the "girdle" pain—"like the pain of toothache"—shortly before the onset of a slight "limp."

The spinal level diagnosis arrived at from a study of the physical signs was confirmed in all cases before operation by lipiodol injection into the spinal canal through the cisterna magna. The injection was made with the patient sitting with his head flexed and chin resting on his chest, novocain being used as a local anæsthetic. The cisterna magna was punctured with a lumbar puncture needle, 5 c.cm. of cerebro-spinal fluid drawn into a syringe, 1·5 c.cm. of lipiodol injected, and 2 c.cm. of the cerebro-spinal fluid then replaced. The spine was X rayed throughout immediately after the introduction of the lipiodol, six hours later, and again 24 hours after the injection.

In Case 2 the normal lumbar curve of the spine was rather straightened, and X ray examination showed some slight lipping of several vertebræ—early spondylitis deformans. In Case 3 there was a slight dorso-lumbar scoliosis with the curve convex towards the left; in all probability, however, this was due to considerable cicatrisation in the right lumbar region resulting from a severe scald in early childhood. In none of the other cases, however, was there any obvious spinal deformity, and X ray examination proved negative.

Slight tenderness on pressure over fifth and sixth dorsal spines was elicited in Case 3, and over eighth and ninth dorsal in Case 6, but no spinal tenderness was discovered in any of the other cases.

The Wassermann reaction in blood and cerebro-spinal fluid of all cases was negative.

The cerebro-spinal fluid, as obtained by lumbar puncture, showed no increased tension and no increase of cells. In Case 2 the protein content was normal, but in all the other cases there was an excess of globulin and a trace of albumin. The fluid showed xanthochromia in Cases 1 and 3 only.

Pathology of the Tumours.

In two cases the tumours were within the substance of the cord—intramedullary—and could not be removed (Cases 4 and 6). Posterior longitudinal chordotomy was done in one of these (Case 6) and the dura left open, but in the other (Case 4) it was not considered advisable, after opening the spinal canal, to incise the cord at that particular stage. Decompression of the cord can be done at a later date when further indications for such procedure arise. In another (Case 5) the growth had originated within the cord, and burst through its posterior aspect and spread within the meninges (intra- and extra-medullary); it was partially removed and the dura left open. The remaining three were found within and growing from the meninges, compressing but not infiltrating the cord—extramedullary—and they were successfully and completely removed. Of the latter, one (Case 3) was a lobulated mass about 1½ in. long, one (Case 1) was about the size of a broad bean, and the third (Case 2) a trifle smaller. In the intramedullary cases the site of the tumour was revealed at operation by a localised bulging of the cord.

The three extramedullary tumours were endotheliomatous, containing psammoma bodies, whereas that which was both intra- and extra-medullary—having burst through from within the cord—appeared to be gliosarcomatous. The pathological nature of the two intramedullary growths, of course, was not determined.

Their Clinical Features.

The principal clinical features of the cases are briefly summarised below. The signs are those present when the patients came under our observation.

Case 1.—Male, aged 27. Four years' duration.

Symptoms.—Gradually increasing difficulty in walking. Feeling of heaviness in, with inclination to drag, the right leg, followed by increasing stiffness. Left leg became similarly affected two years later. Painful flexor spasms in legs began to occur and a burning sensation developed in the form of a band around the waist. One and a half years after this incontinence of urine and fæces set in and three months later the spasticity in the legs had developed to such a degree that he was quite unable to move them.

Signs.—Marked spastic paraplegia. Quite unable to move legs and unable to stand—legs collapsing under him. No gross atrophy. Sensibility to light touch impaired throughout lower limbs and trunk up to level of umbilicus. Band of cutaneous hyperæsthesia immediately above this. Pain and thermal sensibilities unaffected.

Reflexes: Knee- and ankle-jerks greatly exaggerated on both sides with patellar and ankle-clonus. Plantars both extensor. Abdominals: Upper, normal; lower, absent.

Spinal level diagnosis: Tenth thoracic segment.

Lipiodol injection: Lipiodol held up completely as an opaque pear-shaped blob with its base at the level of the disc between the seventh and eighth thoracic vertebral bodies. No change after 24 hours, indicating complete blockage of the intrathecal space.

Case 2.—Male, aged 51. ? Ten years' (or six months') duration.

Symptoms.—Pain in feet and legs—"neuritis of feet"—for ten years, with occasional "giving way" of right leg under him. Nothing more until nine and a half years later—i.e., six months before coming under our observation, when increasing weakness and stiffness began to affect first his right leg and, a month later, his left leg. In another three weeks painful flexor spasms in the legs began to occur, and increased in severity until eventually he was quite unable to straighten his legs. No incontinence or "girdle" pain had developed.

Signs.—Marked spastic paraplegia—flexion spasticity of both legs which was never completely relaxed, but often increased spasmodically and gave rise to much pain. Patient lay curled up in bed. Lower half of abdomen and, at times, upper half were rigid. No muscular atrophy. Some alteration of thermal sensibility throughout lower limbs and trunk up to one inch below umbilicus. Immediately below this level there was a narrow girdle-like band of impaired

tactile sensibility, but elsewhere touch was unaffected. There were no other sensory changes anywhere.

Reflexes: Knee-jerks present, but difficult to elicit, on account of extreme spasticity. Ankle-jerks much exaggerated and associated with clonus on both sides. Both plantars extensor. Abdominals could not be evoked because of the spastic condition of abdominal wall.

Spinal level diagnosis: Tenth thoracic segment.

Lipiodol injection: Lipiodol held up completely in the form of two opaque blobs at the level of the intervertebral disc between seventh and eighth thoracic vertebræ. Twenty-four hours later, however, most of the lipiodol had passed right down to the lower end of the theca indicating an incomplete "spinal block."

CASE 3.—Female, aged 16. Two and a quarter years' duration.

Symptoms.—Persistent pain in right side, at level of costal margin, extending across abdomen towards umbilicus and, later, right round body. Onset of "girdle" pain was followed by slight difficulty in walking—she developed a "slight limp"—which became more pronounced, and gradually the legs became stiff. About two years after onset "tingling" in feet began to trouble her, and then "loss of feeling" in feet and legs gradually became more marked. Urinary and fæcal incontinence developed later after admission to hospital.

Signs.—Complete spastic paraplegia; both legs rigid and extended. Right rather more affected than left. Patient poorly nourished and thin generally. Band of tactile hyperæsthesia, about two inches wide, encircled the trunk at the level of the umbilicus, while immediately below this there was another encircling band, 3½ in. wide, where sensation was impaired. Below this level there was complete anæsthesia to all forms of sensation.

Reflexes: Knee- and ankle-jerks exaggerated on both sides, and well-marked ankle-clonus obtained. Oppenheim's and Gordon's reflexes easily elicited. Upper abdominals present, lower absent.

Spinal level diagnosis: Tenth thoracic segment.

Lipiodol injection: Lipiodol held up in the form of a long tubular opacity with its lower limit at the intervertebral disc between eighth and ninth thoracic vertebræ. Practically no change after 24 hours, indicating complete "spinal block."

CASE 4.—Male, aged 54. 18 months' duration.

Symptoms.—Persistent "burning" pain in left heel and ankle, gradually extending up leg to lumbar region. Six months later weakness and stiffness in legs—particularly the right—with consequent difficulty in walking, set in, and at the same time he experienced numbness and loss of sensation in the right leg from knee downwards. The latter, however, only lasted for three months and was succeeded by a "girdle" sensation—as if being "tied round the waist." Next, painful cramps in feet and legs troubled him, and sometimes flexor spasms of right leg. Eventually urgency of micturition and defæcation developed.

Signs.—Very slight unsteadiness in gait due to slight spasticity in right leg. Occasional flexor spasms of legs on moving feet in bed. No muscular atrophy. Sensibility to light touch impaired throughout left leg and left side of trunk up to a line midway between pubis and umbilicus. Immediately above this line a band of hyperæsthesia to light touch completely encircled the body, and immediately below it a narrow band of hyperæsthesia to pain extended across the abdomen. Below the latter band on the left side sensibility to pain was slightly diminished all down the left leg. On the left side, from immediately above the level of the umbilicus downwards along the left thigh to about three inches below the level of the perineum, finer differences of temperature (epicritic) could not be appreciated, but wider ranges could. Left leg showed diminished sensibility to deep pressure and diminished vibration sense. Vibration sense was also diminished over vertebral spines below first lumbar.

Reflexes: Right knee-jerk exaggerated. Both plantars extensor—slight on left, but very marked on right and associated with active withdrawal of foot. Oppenheim's reflex present on right side only. Abdominals absent.

Spinal level diagnosis: Ninth thoracic segment.

Lipiodol injection: The bulk of the lipiodol was held up at the level of the intervertebral disc between the fifth and sixth thoracic vertebræ. A small quantity, however, passed down to the lower limit of the meninges, leaving a few droplets at intervals on the way down. Twenty-four hours later the appearances were practically the same. A partial "spinal block" was thus indicated.

CASE 5.—Male, aged 50. Twenty-one months' duration.

Symptoms.—Weakness and stiffness, of gradual onset, in right leg, associated with band-like feeling around waist, and followed two months later by similar affection of left leg. Both legs eventually became quite spastic, with calf muscles contracted and feet and toes pointing down, particularly on right side. Abdomen became rigid and he was scarcely able to move about at all. His hands became involved 15 months after onset; his grip became weak, the right first and more markedly affected. Eighteen months after onset he found he "had no feeling" from lower part of chest downwards, and there was a tendency to tonic flexion of both elbows and the fingers of ulnar side of each hand.

Signs: Complete and marked spastic paraplegia. Only able to move toes of left foot slightly and bend left knee. Any attempt at voluntary movement set up increased muscular spasm in legs. Spasms often occurred involuntarily also. Both arms rigid, especially left, with flexor contractions of elbows, wrists, and fingers of both sides. Unable to feed himself. Atrophy of first dorsal interosseus muscles of both hands, and, to a lesser extent, of other dorsal interossei of right. No gross atrophy elsewhere. Almost complete anæsthesia to touch (epicritic) in both legs and trunk up to a line encircling chest about 1½ in. above nipples and crossing second dorsal spine behind, and involving also the second dorsal area on the inside of each upper arm. Complete anæsthesia to pain (pin-prick) throughout left leg and left half of trunk corresponding to the limit of tactile anæsthesia. Over the corresponding area on the right side sensibility to pain was diminished, not absent. Complete loss of temperature sense throughout both legs and trunk corresponding to the area of tactile loss. Vibration sense absent in left leg up to knee, and in right up to junction of middle and upper thirds of tibia. No band of hyperæsthesia.

Reflexes: Knee-jerks greatly exaggerated—particularly the right—and well-marked patellar clonus. Ankle-jerks exaggerated, with well-marked clonus. Both plantars extensor and associated with active withdrawal of legs. Abdominals could not be elicited on account of abdominal rigidity. Supinator jerks active and equal. Biceps and triceps absent. Jaw-jerk absent.

Spinal level diagnosis: Below fifth, but involving seventh and eighth cervical and first dorsal segments.

Lipiodol injection: Most of the lipiodol was arrested at the level of the intervertebral disc between fourth and fifth cervical vertebræ, with three or four small drops lower down in the cervical region. Twenty-four hours later, except for a minute drop at the lower limit of the canal, there was no change, indicating a practically complete "spinal block."

CASE 6.—Male, aged 16. Sixteen months' duration.

Symptoms.—Stiffness, heaviness, and loss of feeling in left leg of sudden onset. Unable to stand. Improved, and after two months was able to walk about with aid of a stick. Two months later could walk unaided—only a slight "limp"—but had occasional flexor spasms of left leg. Came under our care five months after onset.

Signs.—Very slight spasticity of left leg. No atrophy. Band of hyperæsthesia to touch, 2½ in. wide, encircling body at level of eighth, ninth, and tenth dorsal spines behind and passing downwards and forwards across the umbilicus, more marked on left side. Sensibility to touch and pain slightly diminished throughout left leg, and just below left knee thermal sensibility was disturbed over a small area.

Reflexes: Knee-jerks—left exaggerated, right not exaggerated. Patellar clonus on left side, no ankle-clonus. Plantars—left extensor, right flexor at first, but later became extensor. Lower abdominals less brisk than upper.

Operation was advised, but strenuously refused by patient's mother, and he was removed from the hospital. He remained very well and even resumed work, but 11 months later he again suddenly lost the power in both legs and developed incontinence of fæces and retention of urine with overflow. Five days later he was sent into the wards, and the following condition was found.

Signs.—Complete paraplegia, with spasticity more marked in left leg. Occasional involuntary flexor spasms of left leg. Sensibility to light touch (brush) absent throughout right leg up to level of great trochanter and in left up to a line just below this. From these levels up to a line midway between umbilicus and ensiform, and passing across eighth dorsal spine behind, appreciation of light touch diminished. Thermal sensibility lost in both legs and impaired above over an approximately corresponding area. Appreciation of pain (pin-prick) absent in legs, and diminished above up to about one inch below the umbilicus. Vibration sense absent in both legs.

Reflexes: Knee-jerks—left exaggerated (with patellar clonus), right present, not exaggerated. Both plantars extensor. Upper abdominals present, lower absent.

Spinal level diagnosis: Probably first lumbar segment with some extention or pressure effect upwards to the ninth thoracic.

Lipiodol injection: Lipiodol held up completely in the form of two opaque lateral columns diverging below—their lower ends being at the intervertebral disc between the tenth and eleventh thoracic vertebræ. Twenty-four hours later the lower half of the right column of lipiodol had remained in situ, but its upper half, together with that of

the left side of the cord, had passed downwards to the cul-de-sac at the lower end of the meninges, leaving a few irregular blobs scattered throughout the canal along its tract of descent. A partial "spinal block" was thus indicated.

Commentary.

Cases 1 and 2 were operated upon under intratracheal ether, the remaining four under nitrous oxide and oxygen. The latter method was adopted because Case 2 succumbed to widespread purulent bronchitis 10 days after operation. The remaining five all made good recoveries and left hospital much improved.

In performing the laminectomy a longitudinal incision was used in all cases, its centre being made to correspond with the spinal level diagnosis. In one case three laminæ were raised, in another five, and in the remainder four. Before removing the laminæ the soft parts were protected by rubber sheets, and at intervals throughout the operation a stream of warm saline was used to irrigate the wound. Fine silk sling sutures having been passed through the dura, the latter was opened longitudinally. In those cases (1, 2, and 3) from which the tumours were removed, and also in Case 4 (a small intramedullary tumour) the dura was subsequently closed with fine cat-gut, but in Cases 5 and 6 it was left open to permit of greater decompression. In Case 3 three posterior roots had to be cut before the tumour could be removed.

Cases 1 and 2 were nursed lying on their backs after operation, but the others were kept prone for about a fortnight to avoid pressure on the wound. In order to accustom the patients to this posture they were made to practise it for several days before the operation.

PASSIVE IMMUNISATION AGAINST SCARLET FEVER.*

By EDWARD JAMES, M.B. Aberd., D.P.H.,
LATE SENIOR ASSISTANT MEDICAL OFFICER, PLAISTOW HOSPITAL.

From time to time scarlet fever makes its appearance in wards not intended for sufferers from that disease, both in isolation and in other hospitals, where, apart from the possible consequences to those infected, it may interfere seriously with the admission and discharge of patients. In scarlet fever antitoxin we have at our disposal a means of producing a passive immunity, temporary but valuable, in patients exposed to infection. Comparatively little has been published in this country on the amount of antitoxin adequate for protection. This can be ascertained only by using varying quantities in different series of patients, for, in the absence of any certain method of standardisation, different batches of antitoxin may vary considerably in antitoxin content. Now it is practically certain that no Dick-negative person will develop scarlet fever. Hence, if Dick-positive reactors can be rapidly made Dick-negative and kept negative even for a few days, not only could an outbreak of scarlet fever be limited, but an effort could be made, during this brief period of immunity, to trace and deal with the source of the original infection. The ability of a scarlet fever antitoxin to produce and to maintain passive immunity as measured by the Dick test provides us with a rough method of estimating its antitoxic content, but this passive immunity method must be correlated with other methods before we can hope to arrive at a sound method of standardisation.

In this investigation I have limited my work to an attempt to determine the amount of antitoxin sufficient to protect susceptible contacts of scarlet fever for a period of seven to ten days. I have chosen this period for two reasons: first it is unlikely that a patient, who has been rendered Dick-negative within a few hours of exposure to infection, will develop scarlet fever if that passive immunity is maintained beyond the period of incubation; secondly, although a period of 14 days might be safer, the amount of antitoxin required for this is probably more than twice that which is adequate for a period of seven to ten days. Part of this work was done in wards where no scarlet fever had occurred, but latterly the appearance of an occasional case of that disease among diphtheria convalescents made it necessary to prevent the spread of infection by producing passive immunity in susceptible contacts. It may be urged, of course, that outbreaks of scarlet fever in diphtheria wards are usually limited to one or two patients, and that passive immunisation is therefore unnecessary. It can never be certain, however, that scarlet fever will not spread more extensively, and it seems only reasonable to make use of a preventive measure which is both simple and effective.

In the following experiments scarlet fever antitoxin was given intramuscularly to several series of Dick-positive diphtheria convalescents. Dick re-tests were carried out in 24 hours on all patients; in 48 hours in those who were still positive at the first re-test, and subsequently at weekly intervals until they again became Dick-positive, or for as long as their stay in hospital would allow. In dealing with a diphtheria ward where scarlet fever had made its appearance, all the contacts were immediately Dick-tested, and antitoxin was given to the positive reactors. Re-tests were made at similar intervals. Except where otherwise stated, the Dick toxin employed was a 1/1000 dilution of ×48.

Table I. shows the results obtained in a series of ten children with a dose of 5 c.cm. of an unconcentrated serum (A). This table shows that only four out of ten were rendered Dick-negative in 24 hours, and that the remaining six were still positive in 48 hours. All ten were positive at the end of seven days. 5 c.cm. of this serum, therefore, was quite an inadequate dose.

TABLE I.

Serum.—Type A; dose 5 c.cm.

No.	Age.	Re-tested in— 24 hrs.	48 hrs.	7 days.
1	5	+	+	+
2	3	0		+
3	4	0		+
4	4	+	+	+
5	2	0		+
6	3	+	+	+
7	3	0		+
8	6	+	+	+
9	3	+	+	+
10	2	+	+	+

TABLE II.

Serum.—Type A; dose 10 c.cm.

No.	Age.	Re-tested in— 24 hrs.	48 hrs.	7 days.	14 days.
1	5	0		0	+
2	4	0		0	+
3	2	±	0	±	+
4	2	0		0	+
5	2	0		0	+
6	6	0		0	+
7	3	0		±	
8	2	±	±	±	
9	4	0		+	
10	3	±	0	±	

Table II. shows the results in a series of ten children with a dose of 10 c.cm. of the same serum. In this experiment seven patients out of ten were rendered Dick-negative in 24 hours, and two of the other three in 48 hours. Five were still negative at the end of a week, but all ten had become positive in 14 days. We may therefore conclude that even 10 c.cm. of this unconcentrated serum was an inadequate dose, and that the amount of such a serum necessary to keep patients Dick-negative for seven days would be too great to be of practical value.

Table III. shows the effect of a concentrated serum (B), given in a dose of 2·5 c.cm. to ten children in a diphtheria ward within 24 hours of the occurrence of a case of scarlet fever. This table shows that all ten patients were rendered Dick-negative in 24 hours and remained so for at least seven days, thereafter becoming gradually positive once more. It also indicates the difference between tests made with toxin dilutions of 1/1000 and 1/500 at periods of 7, 14, and 21 days after administration of antitoxin. Theoretically, at least, this serum was much more satisfactory than its predecessor.

* Part of a thesis submitted to the University of Aberdeen for the degree of M.D.

Case 1 was faintly positive when tested 14 days after immunisation and developed a mild attack of scarlet fever five days later. It is interesting to note that the area of skin on which the Dick tests had been made was not invaded by the rash, while it was surrounded by a bright erythematous ring of greater intensity than the eruption on the forearm. This phenomenon has been noted by Zingher,[1] who attributes the pale area of skin to the development of a local immunity in response to the Dick toxin, the surrounding ring of erythema being due to the sensitised condition of cells containing only a minimal amount of antibody to the scarlet fever toxin. Two further Dick tests were made on this patient on the second day of the eruption, one on the immune area of skin on the forearm, the other about two inches outside this zone. No reaction appeared at the site of the first, while the second was positive. A final re-test on the tenth day of illness was negative.

TABLE III.

Serum.—Type B; dose 2·5 c.cm.

No other patient in this series developed scarlet fever while in hospital.

That 2·5 c.cm. of a concentrated serum is not always sufficient to keep patients Dick-negative for seven days is shown by Table IV., illustrating an experiment where that amount of two other concentrated sera (C and D) was given to 18 Dick-positive children in a diphtheria ward, 24 hours after the occurrence of a case of scarlet fever therein.

D. = Discharged.

Both these sera failed to make all the children in the respective groups Dick-negative in 24 or 48 hours, and eight of them were positive after seven days. Unfortunately some of these patients were discharged from hospital, so that re-tests in 14 days were impossible, but four out of five were still negative after that period. One of these, however, developed a mild attack of scarlet fever 21 days after the injection of antitoxin, but I am unable to say whether he had by this time become Dick-positive. Case 10, who did not become Dick-negative, was discharged from hospital 11 days after receiving antitoxin, but was readmitted ten days later on the fourth day of a mild attack of scarlet fever. A Dick test on this patient on the following day was negative.

In view of the comparative failure of these sera in a dose of 2·5 c.cm., a further trial was carried out with them in another diphtheria ward where a case o scarlet fever had just occurred. This time a dose o 5 c.cm. was used, and the results are shown in Table V With the striking exception of Case 3 all thes

patients became Dick-negative in 24 hours an remained so for at least seven days. Of six whor I was able to re-test in 14 days, four were still negative

Case 3 originally gave a strongly positive reaction. Nin days after receiving antitoxin he developed a mild attack c scarlet fever. During the eruptive stage he showed blanche areas of skin at the site of the previous Dick tests, but n surrounding ring of erythema. A Dick test on the tent day of illness was negative, while his blood serum, taken o the twenty-sixth day, gave a good Schultz-Charlton reactio

Case 2 was discharged from hospital 18 days aft immunisation, but was readmitted 28 days later on th third day of a moderately severe attack of scarlet feve During her initial stay in hospital she had six Dick test performed on the flexor surface of the right forearm, the ski of which now presented an unusual appearance. Over a oval area 5 in. long by 2 in. broad there was profus desquamation, the underlying skin being deeply pigmente while surrounding it was a bright erythematous ring. Th rest of the forearm was invaded by a typical scarlet feve rash. Fourteen days later this area of skin looked quit normal, while typical desquamation was in progress ov the remainder of both upper extremities. The mother c this child volunteered the information that the zone c skin described above had become a vivid red colour about day before the rash began to appear on the neck and ches

Brown[2] also noted this reappearance phenomeno in a few patients, but was unable to confirm Zingher observation that in such cases the site of injection c Dick toxin presented a blanched appearance. He doe not state, however, the time which had elapse between the performance of the Dick test and th onset of scarlet fever, and it is here, I believe, that th explanation of this apparent discrepancy is to b found. In the two cases quoted by Zingher th interval of time was respectively four and seven days in the first two which I have described it was respe tively five and two days, while in the third instance was 29 days from the date of the sixth test and co siderably longer from that of the previous five. W may therefore say, I believe, that when scarlet feve supervenes within a few days of the performance of Dick test, the area of skin affected is still immune an is accordingly not invaded by the eruption. Whe however, a period of three to four weeks has elapse the skin of this part has passed from a state c immunity to one of hypersensitivity to the scarle fever toxin, and the first cutaneous manifestation c infection occurs—in an exaggerated form—in thes hypersensitive cells.

Conclusion.

In these experiments scarlet fever attacked onl those patients who were not rendered Dick-negative c who became Dick-positive after a varying period c immunity. Unconcentrated sera were found to be c little or no value, while of three different concentrate sera one was sufficiently potent to keep ten patien Dick-negative for at least even days in a dose c 2·5 c.cm. This dose has to be doubled in the case c

he other two concentrated sera, and even then one atient remained Dick-positive.

I believe, therefore, that 5 c.cm. of a concentrated carlet fever antitoxin is usually sufficient to protect usceptible contacts for a minimum period of seven ays. It is probable, however, that a dose of 10 c.cm. s necessary in those who give a very strongly positive)ick reaction, although further evidence is required on his point.

I am indebted to Dr. D. MacIntyre, medical superintendent, Plaistow Hospital, for permission to record his work, and to Dr. R. A. O'Brien, of the Wellcome Research Laboratories, for supplying me with the necessary toxin and antitoxin.

IRRADIATED ERGOSTEROL IN THE TREATMENT OF RICKETS.

By R. AIDIN, M.D. Dub.,
LATE ASSISTANT MEDICAL OFFICER, ALDER HEY CHILDREN'S HOSPITAL, LIVERPOOL.

During the past decade there have been great dvances in the treatment of rickets, advances in art empirical and in part founded on recent progress n the theoretical knowledge of the disease. Treatment s in a condition of flux; a few years ago the value of diet rich in antirachitic vitamin was stressed; last ear actinotherapy was hailed as the ideal; to-day, he oral administration of artificially prepared concentrated antirachitic vitamin is being tried and bids air to become the standard treatment of the future. Rickets can be cured by many different means; ntirachitic diet, cod-liver oil, heliotherapy, actinotherapy, and the oral administration of concentrated ntirachitic vitamin have all been used. The length f time necessary to effect a cure differs widely ccording to the method of treatment, the patient's ge, and idiosyncrasy. The rapidity with which a ure can be effected is important, for not only is the hild's period of invalidism shortened and the risk of ntercurrent disease due to lowered resistance reduced, ut the danger of deformities is minimised.

That rickets is caused by a deficiency in the body f the antirachitic vitamin D is now generally agreed. Both the antirachitic vitamin and ultra-violet light an protect against rickets. The vitamin must be ncluded in the food; ultra-violet light, whether atural or artificial, can act either through the food r directly on the body. The light acts on the ro-vitamin contained in the food or else on the ro-vitamin normally present in the cutis vera, onverting it into the active antirachitic vitamin.[1]

Ergosterol, a sterol originally prepared from ergot, s widely distributed. The recent work of Rosenheim nd Webster[2] has shown that after irradiation rgosterol becomes very powerfully antirachitic. The work of these observers suggest that ergosterol s the pro-vitamin and that irradiation converts it nto the actual antirachitic vitamin. The British)rug Houses prepare a suspension of irradiated rgosterol and call it "Radiostol." This preparation as used in the treatment of the patients described n this paper. Their general condition improved oncurrently with the radiological evidence of healing f the epiphyseal lesions, although deformities were ot improved.

Radiographic Evidence of Cure.

It is difficult to appraise the curative properties of ny particular method of treatment. In the following bservations reliance has been placed on radiograms f the wrist, both in diagnosis and in determining he cure. E. Mellanby[3] has shown that radiograms resent a true criterion of the disease in animals. n order to make a comparison possible between the esults of different methods of treatment an attempt as been made to keep uniform the standard of iagnosis and cure. In children the clinical cure is lways, I think, preceded by the healing of the bony lesions. This process may be visualised in serial films taken at frequent intervals. It must be borne in mind, however, that the radiological evidence of healing of the bony lesions is not always followed by a clinical cure, for after calcification of the epiphyses is complete, the square head, bowed legs, and enlarged radial epiphyses not infrequently remain, and may persist for many months. Apart from these gross stigmata, the clinical improvement that follows the process of healing, visualised in serial radiograms, is very striking. A child suffering from active rickets adopts the motionless Buddhaesque pose and contemplative mien of the saint; a radiogram of the wrist shows active rickets. After a few weeks' treatment by one of the newer methods the child becomes active and lively, jumping about in his cot and keeping up a continual chatter of baby talk; a radiogram now shows that healing is well advanced.

The earliest structural changes that occur in rickets take place in the cranial bones and at the costochondral junctions; at the present stage of radiographic technique these cannot be photographed. The radiogram of the wrist shows changes only when the disease has passed its earliest stage; the first signs are slight fuzziness at the distal end of the ulna followed by splaying of the distal end of the radius and accompanied by a varying degree of osteoporosis. In the more advanced stages both the epiphyses and the diaphyses are affected. The former is smaller than normal, more irregularly ossified, and separated from the diaphysis by an abnormally wide and ill-defined zone of proliferation. The end of the diaphysis is broader than normal and shows evidence of disordered and irregular growth. It may show cupping and fraying. The medullary cavity is wide and translucent to the rays. Healing is shown by the increasing density of the bone shadow, the ossification of the epiphysis, the filling-in of the concavity at the end of the diaphysis, and finally by the thin white line characteristic of healed rickets.

Clinical Records.

The dose of radiostol used at first was three minims thrice daily; later it was increased to ten minims thrice daily, administered in a suspension of mucilage. None of the patients showed any signs of intolerance. No cod-liver oil was given; the patients were treated indoors in a hospital ward.

Case 1.—On admission this patient, a male infant aged 1½ years, showed clinically active rickets. A radiogram of the wrist showed slight fuzziness of the distal end of the ulna and splaying of the end of the radius, together with slight osteoporosis—conditions indicating early rickets. Three weeks after the commencement of treatment with radiostol a radiogram showed definite evidence of healing, increased density of the bone shadow, and clear definition of the ulna and of the radial epiphysis. During the treatment the general condition improved markedly and the infant gained weight rapidly.

Case 2.—On admission this patient, a girl aged 1 year and 8 months, suffered from active rickets. A radiogram of the wrist showed moderately severe bony lesions. A radiogram taken four weeks after the commencement of treatment showed that healing had occurred.

Case 3.—On admission this patient, a boy aged 1 year and 9 months, suffered from active rickets. A radiogram showed very severe bony lesions at the wrist, indicated by cupping and fraying of the ends of the diaphyses of the radius and ulna. A radiogram taken eight weeks after the commencement of treatment showed that the bony lesions were almost healed. The child's general condition also improved.

Case 4.—When admitted this patient, a girl aged 3 years and 9 months, suffered from active rickets and a marked varus deformity of the lower limbs. A radiogram of the wrist showed moderately severe rickets, indicated by splaying and fuzziness of the ends of the diaphyses of the radius and ulna, and a marked degree of osteoporosis. A radiogram taken six weeks after the commencement of treatment showed that the bones were almost normal in consistence. The child's general condition had improved, but the deformities of the lower limbs were practically unaltered.

Case 5.—On admission this patient, a boy 3½ years old, showed very marked lateral bowing of both tibiæ. A

radiogram of the wrist showed very severe rickets. He was given massage and daily moulding, immobilised with Liston splints, and treated with radiostol. Six weeks after the commencement of treatment there was definite radiological evidence of healing which was completed four weeks later. The bony deformities of the legs, however, were practically unaltered.

The last two cases are instructive, as they illustrate an incorrect method of treatment. These patients, who both showed marked deformities, ought to have been given no specific antirachitic treatment until the deformities were cured. All clinicians who make a routine radiological examination are aware that active and severe rickets is not infrequently present in a patient suffering from marked deformities. It is a mistake to treat such a patient with any method that rapidly produces calcification of the bones, for the deformity is thus stabilised, the natural curative process of growth is retarded, the corrective effect of massage and moulding is decreased, and osteotomy is more often necessary.

The Time Element.

For comparative purposes the results obtained at Alder Hey Hospital by other methods of treatment are of interest. It was found [4] that cod-liver oil and malt and antirachitic diet effected a cure in a radiologically severe case in approximately 15 weeks; exposure to the rays of a carbon-arc lamp in addition, did not appreciably hasten healing; exposure to the rays of a tungsten-molybdino-core carbon arc, in addition to cod-liver oil and diet effected a cure in approximately nine weeks; while exposure to the rays of a new mercury-vapour lamp and the administration of irradiated cholesterol with cod-liver oil and diet, together effected a radiological cure in approximately five weeks. Several of the patients treated with radiostol received too small doses at the commencement of the treatment.

Actinotherapy in the treatment of rickets is rapidly becoming a thing of the past; for in irradiated ergosterol the pædiatrician possesses a potent antirachitic agent, more effective than cod-liver oil, and when administered in sufficient doses, probably more effective than artificial ultra-violet rays, and certainly simpler and more economical in practice.

I wish to thank Lieut.-Colonel P. Macdiarmid, M.D., medical superintendent of Alder Hey Children's Hospital, for permitting me to publish these cases.

Clinical and Laboratory Notes.

TWO CONSECUTIVE ABDOMINAL PREGNANCIES.

BY MILLICENT V. WEBB, L.R.C.P. & S. EDIN.,
WOMEN'S MEDICAL SERVICE FOR INDIA; PRINCIPAL, WOMEN'S MEDICAL SCHOOL, AGRA, INDIA.

THE following case appears worthy of note, as two consecutive abdominal pregnancies in the same patient must be extremely rare.

A Hindu woman, aged 35, was admitted to the Maternity Hospital, Agra, on March 1st, 1924, complaining of enlargement of abdomen and amenorrhœa for one year, followed by blood discharge for one month. Eight children; two alive. Last child two years ago.

On examination the abdomen was found to be enlarged by a tumour the size of a full term pregnancy; tumour was very hard in places, but definite fœtal parts were not palpable, owing to rigidity of the abdominal muscles. No fœtal heart sounds were heard. On vaginal examination the tumour was found to extend into the pelvis, which appeared to be filled with a soft solid mass. A provisional diagnosis of ovarian tumour was made.

On opening the abdomen on March 4th a thick wall, like that of a malignant ovarian cyst, presented. A child's foot was felt through a thinner portion of the sac, and a dead full term child was removed. The child had obviously been dead for some time; the placenta, situated in the lower abdomen and pelvis, was partially dried up and thus easily shelled off. Probably the history was correct and the child had been dead three to four months. Oozing was stopped by adrenalin solution. Much of the sac had to be left *in situ*; its edges were drawn together in the lower part of the wound, and tube and packing were inserted. The abdomen was closed, except in the lower 2 inches, by through-and-through silkworm-gut stitches. On March 5th the packing was removed and tube changed under chloroform. The tube was left out on the seventh day, and patient was discharged cured after three weeks.

On June 4th, 1926, the same patient was again admitted into the Maternity Hospital, complaining of pain in the back and lower abdomen. It happened that every member of the staff who knew her history was on leave. As she gave a definite history of a child taken out per abdomen, and as Cæsarean sections are extremely common, her old notes were not looked up. She said she was about seven months pregnant, had had strong pains for three days, and had felt no fœtal movement after the pains stopped.

On examination the uterus appeared enlarged to the size of a 6½ months pregnancy; os closed, cervix soft, pulsation in the fornices. Fœtal parts not distinctly felt; this may have been due to thickening from the old sac. There was no indication for immediate emptying of the uterus. Patien left hospital after six days, and was told to return.

On Nov. 15th, 1926, patient was admitted into th gynæcological ward with a history of pain in the abdome and offensive, blood-stained, purulent vaginal dischar for three months following amenorrhœa. She gave a history of having been in the maternity ward in June, b was recognised as having had an abdominal pregnancy tw years previously, and her old notes looked up. There w slight fever. On examination a mass was felt reaching the umbilicus, hard and tender, very slightly movable. O vaginal examination a large, hard uterus was felt, surrounde apparently by a mass of inflammation, and adherent to th old scar; purulent discharge from the cervix, but no su gestion of a collection of pus, or any indication for oper tion. Diagnosis of chronic inflammation was made, pr bably originally due to an infection of the portions of s which had been left after the operation. Patient w treated on the usual lines, but only remained ten days hospital as she felt better and discharged herself.

On March 15th, 1927, patient was admitted into th septic surgical ward for a discharging sinus in the abdome She refused any operation and left at once.

On April 4th, 1927, she was readmitted as a septic surgic case. There was thick, very offensive pus discharge fro the old scar and the inflammatory mass below it. On th 8th an incision was made and the sinus investigated. Th first thing which appeared was the humerus of a five mont fœtus. The rest of the bones were removed and the cavi carefully swabbed out and drained. On the third day fæcal fistula developed; this persisted for about a mont but finally closed, and on May 26th the patient was d charged cured with wound completely closed.

This case illustrates well the difficulties und which work is done in India, where patients refu treatment and take their own discharge, and the is no antenatal organisation. At the first operati it was not possible to disturb the parts to find o which tube had ruptured, and the patient insist on going out directly the wound healed before th pelvic organs could be separately palpated biman ally. I did not see her again till she appeared tw and a half years later with a hard inflammatory ma reaching to the umbilicus, giving no history pregnancy subsequent to the operation or of havi been in the maternity hospital five months previousl

Full term abdominal pregnancies are comparative common in India. During 17 years' operative wo in women's hospitals in Delhi, Calcutta, and Agra have had four. The first was full term with a li child. On abdominal inspection the outline of th child's fingers could be seen beneath the abdomin wall; in this case the pregnancy had occurred fir in the left tube and secondarily in the broad ligamen from which it had ruptured into the abdomin cavity; the placenta was folded on itself and almo

pedunculated, and was easily tied off. The child had double talipes and marked torticollis; though delivered with pulsating cord it did not live. The mother, who had been doing hard labour as a coolie woman all through her pregnancy, made an uninterrupted recovery.

The second case, also full term, came in with false labour pains; abdominal pregnancy was diagnosed, and I operated instead of waiting as I now should. The thinned-out placenta was attached to the whole anterior abdominal wall, from costal margins to pubes, and the patient died on the table from uncontrollable hæmorrhage.

The third fœtus had been dead some months and had a thick sac very similar to the case first described. Recovery was uneventful.

A CASE OF LABOUR WITH COMPLETE OCCLUSION OF THE EXTERNAL OS.

By E. O. Croft, M.D. Durh., M.R.C.S. Eng.,
SENIOR SURGEON, HOSPITAL FOR WOMEN, AND OBSTETRIC SURGEON, LEEDS MATERNITY HOSPITAL;
AND
A. M. Claye, M.D. Leeds,
TUTOR IN OBSTETRICS, UNIVERSITY OF LEEDS; AND RESIDENT MEDICAL OFFICER, LEEDS MATERNITY HOSPITAL.

Cases of occlusion of the cervix uteri during labour are of sufficient rarity to be worthy of record, and the following is an interesting example.

The patient was admitted to the maternity hospital on August 5th, 1927, after a car ride of over 40 miles. She was a 4-para who had had three previous normal labours. On admission the pulse-rate was 88, temperature 98·4° F., and general condition good. She had been in labour since the previous afternoon. On abdominal examination the vertex was found presenting in the left occipito-anterior position, the head being deep in the pelvis and well flexed. On vaginal examination the head was found to be completely covered by the distended walls of the cervix. There was a slight linear mark about half an inch long in the most dependent part, but no opening whatever. A crucial incision, with its centre over the mark, was made; the liquor amnii at once escaped and the head was felt. Complete dilatation rapidly followed and a stillborn female child, deeply stained with meconium, was easily delivered with forceps. The cervix was sutured with catgut, leaving an opening in the centre.

On discharge from the hospital the cervix appeared normal and duly patent.

The patient had a history of prolapse, the cervix (?) coming outside the vulva, during early pregnancy. The probable explanation is that ulceration of the prolapse with healing and contraction took place after conception.

A good account of the complication is given by Spiegelberg,[1] who refers to the old term "conglutinatio orificii externi" of Naegele, and distinguishes the results of cicatricial inflammatory closure from those due to a collection of inspissated epithelium in which no scar tissue is present. The latter condition can be easily broken through without incision. R. Barnes[2] reports a case in which the os was completely closed by cicatricial tissue contracting concentrically. Severe labour pains failed to open it. He incised the centre of the scar and nicked freely all round. The cervix expanded with wonderful rapidity as soon as the unhealthy tissue was divided. In cases of stenosis without complete occlusion the dilatation of the cervical walls occurs mainly at the expense of the anterior wall, so that the small external os is displaced high up and backwards. In the present case the posterior wall was relatively more distended, and the small scar was easily accessible below and in front. In the case of a young primipara under my care (E. O. C.) some years ago there had been primary elongation of the cervix, and where labour had been prolonged many hours no cervical aperture could be detected. Under anæsthesia, however, a minute depression was found high up and looking backwards. A small surgical probe penetrated this, and the opening was gently drawn down and held in a more correct position relative to the uterine axis. Dilatation and delivery proceeded rapidly and normally. This was probably a condition of "conglutinatio" (Munro Kerr illustrates a similar case[3]). In both my cases the "wonderful rapidity" mentioned by Barnes was very striking.

TREATMENT OF OBESITY BY ULTRA-VIOLET RAYS.

By C. L. Williamson, M.R.C.S. Eng.,
AND
C. H. Broomhead, M.D. Manch., M.B., B.S. Lond.

We hope that the following details may be of interest to medical men who include ultra-violet light in their therapeutic armament. Dr. Howard Humphris in his admirable text-book "Artificial Sunlight and its Therapeutic Uses," makes the following remark:—

"I do not recommend the treatment of obesity by ultra-violet light. Electricity has other and better means at its disposal than this; but, as it is a state of disordered metabolism, accompanied by superfluous deposits and various functional disturbances, it is interesting to note that an agent such as ultra-violet light, which profoundly and beneficially affects metabolism, does so in a disorder which is so basically metabolic."

Conclusive evidence of the beneficial effects referred to by Dr. Humphris is given in the following case.

Our patient was an obese man aged 52 years; his personal habits were temperate. His occupation required him to travel a great deal, and he seized every opportunity of walking, but no reduction in weight resulted. He complained, apart from the "burden of the flesh," of dyspnœa and palpitation. There was a slight increase in the area of cardiac dullness to the left. No bruits were detected. The blood pressure was normal for his age and there was no protein in the urine. Numerous extrasystoles were present. His course of ultra-violet irradiation consisted, in all, of 49 exposures, the first ten being given twice weekly and the remainder, owing to the pressure of his business engagements, once a week. For each dose he was stripped to the waist only. The first 28 irradiations were administered by the tungsten arc with the mirror reflector and began with an exposure of three minutes each on the back and front of the body at a distance of 18 in. from the electrodes, gradually increased to a maximum of eight minutes each, back and front, at the same distance. The twenty-ninth to the forty-ninth doses were all given with the air-cooled "Uviator" lamp made by Messrs. Kelvin Bottomley and Baird, and ranged from an initial exposure of three minutes each, back and front, at 24 in., to five minutes at 12 in., the ammeter registering 2·75 amps. The result was interesting. After the thirteenth dose the extrasystoles vanished and did not return. The alteration in weight was even more noteworthy. The weighing was carried out by the patient himself, a very intelligent man, upon the same pair of scales which were tested at frequent intervals. He was weighed in the same clothing and at the same time of day at weekly intervals. Before treatment he scaled exactly 238 lb. After the first six doses he had dropped to 230 lb. The twenty-sixth dose had reduced him to 212½ lb. From the twenty-seventh to the forty-ninth applications he received, in addition to the light, a mild weekly dose of faradism, applied chiefly to the abdomen. At the conclusion of treatment his weight had fallen to 194½ lb., a loss of 43½ lb. in all. The decrease was not invariably progressive. On four occasions there was a gain over the weight of the previous week, but never of more than one pound, and on five occasions the weight was unchanged. No special dieting was carried out nor were any drugs, except a simple "after-dinner" aperient pill, taken. The general health improved progressively, and the patient cheerfully purchased new suits of clothes as his old ones fell, in more or less graceful folds, upon his body. His 19-inch collar was replaced by one of 17½ in. Three months after his last visit to us his weight was 193½ lb. and he was feeling remarkably well.

The title of this article may be objected to as misleading, since electricity was also employed. It is, however, to be noted that before faradism was applied

he had already lost 25½ lb. in weight. So far as we are aware the principal modern treatment of obesity by electricity alone is by the Bergonié method, which involves rather costly apparatus. It is, of course, not to be inferred that ultra-violet light is an infallible remedy for adiposity, but we suggest that it is feasible, pleasant, and harmless. We feel convinced that better results have been obtained by other actinotherapists, and it would be of interest if they could be recorded.

Liverpool.

Medical Societies.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

AT a meeting of this Society held on Jan. 27th Sir HUMPHRY ROLLESTON, the President, took the chair, and Dr. DAVID NABARRO opened a discussion on the

ANTENATAL TREATMENT OF SYPHILIS.

It did not come within his province, he said, to see women during and immediately after gestation, and to present the material needed for his purpose it had been necessary for him to read through a great deal of the work of others. Since doing so he had become aware of the valuable article recently published on the subject by Boas, of Copenhagen.

It was only comparatively recently that the attempt to prevent congenital syphilis by treating the mother during pregnancy had been revived; no reference was made to it, for instance, in the large work on syphilis by D'Arcy Power. Three groups of cases should be borne in mind. In the first group were people infected with syphilis who wished to marry. No one so infected should be allowed to marry unless two years of adequate treatment, dating from the primary sore, had been received; and even then consideration must be given to a number of other factors. In the second group were those who contracted the disease after marriage, symptoms showing themselves in either partner. In these circumstances both partners should receive energetic treatment, for their own sakes and for that of probable offspring. The mother should be warned against conceiving a child sooner than six months after commencing treatment. If she was already pregnant there should be no delay in beginning antisyphilitic measures. The third category comprised those women who, though presenting few or no signs of the disease, gave a history of one or two miscarriages. They should be treated as soon as possible in the pregnancy and should have similar attention at each succeeding gestation.

The first centre in this country for treating venereal disease had been established by John Adams in Thavies Inn, and there the antenatal treatment of syphilitic mothers was very successful, the last 37 women treated having given birth to 37 living infants. Without following up the cases further it could not, however, be said that all these children were free from infection. The statistics of J. W. Williams, of Johns Hopkins Hospital, showed that syphilis appeared in 49 per cent. of the offspring of 169 untreated pregnant women, in 39·2 per cent. of those of 102 inefficiently treated women, and in 6·7 per cent. of the children whose mothers, 179 in number, had been properly treated during pregnancy. Hence it was clear that even efficient treatment of the mother did not make it certain that the issue would be a healthy child. It must also be remembered that though a placenta looked healthy, the child might be syphilitic. The percentage of syphilitic children born after the mothers had been efficiently treated, taken over a series of years, varied between 3·7 and 7·7.

Methods of Treatment.

The older practitioners, said Dr. Nabarro, had t choice of using either mercury or iodide of potassiu Some preferred not to treat the mother duri pregnancy because they feared abortion. Salvarsa or its substitutes, seemed best, though Boas and h colleague Gammeltoft considered that the best resul in their hands followed the use of silver-salvarsa Whatever drug was chosen the great need was th the treatment should be efficient. Most of D Nabarro's cases had had novarsenobillon. Bo supplemented the silver-salvarsan by mercuri inunction; he gave six or eight injections of silv salvarsan, and after a month's rest from treatment further course, with mercurial inunction. Anoth rest brought the patient to the middle of the pregna period, the time when, it was generally agreed, t spirochætes began to wander through the placenta a infect the fœtus. At such a time there should be access of energy in the treatment. Dr. Nabarro sa he had been content to treat expectant mothers w came to him on the same lines as an ordinary case i.e., by giving weekly injections of N.A.B. with exa ination of the urine before beginning treatment, and monthly intervals to make sure that the kidneys we working properly. Tartar and sepsis of teeth or mou must always be put right. For pregnant mothers started with only 0·3 g. of N.A.B., working up to 0 and the course was repeated as often as possible duri gestation. If oral administration of mercury was fou to do as much good as injections it should be adopt in preference as it was more convenient. Wi regard to treatment in succeeding pregnancies, it mu be borne in mind that, even in the absence of tre ment, the intensity of the syphilitic infection seem to diminish, so that after repeated gestation t tendency was for the offspring to be born healt Still, a woman could give birth to a syphilitic ch 20 years or more after her one infection with t disease; in one case this happened 37 years aft wards, the disease in that case having been contract in childhood. Dr. Nabarro raised the interesti question whether treatment of mothers duri pregnancy might prolong the period during which th could give birth to syphilitic children. Often only small amount of treatment of the mother had be found to ensure that her child should be healt Prof. F. J. Browne and others advocated t compulsory notification of pregnancy. Possibly th might come sometime in the future as a result education, but the speaker thought there would grave objections to it at the present time. Mu could be done by the establishment of sufficient V clinics for pregnant women in all large cities, and h could be given by maternity and child welfare centr

Colonel L. W. HARRISON devoted his attention the question whether it was worth while to mak bigger effort than at present to reduce the incidence congenital syphilis by the antenatal treatment expectant mothers, and, if so, along what lines th effort should be directed. There was now availa overwhelming evidence that if it were possible place every syphilitic pregnant woman under tre ment, congenital syphilis would almost vani Whatever amount of treatment such mother mi have had before pregnancy she should be trea during pregnancy. It had been calculated that 16 cent. of stillbirths were due to syphilis, and for seven years 1920–26 there were 25,000 stillbirths this country. The Departmental Committee on Causes and Prevention of Blindness concluded t syphilis was the direct cause of 10 to 15 per cent. the blindness at present existing in this country, wh many other cases of sight failure were due to degene tive changes consequent on vascular disease possibly syphilitic origin. In March last 46,822 bl persons were registered in England and Wales—i "too blind to perform work for which eyesigh essential." 16,000 syphilitic pregnant women annum stood in need of treatment, but nothing this number were being treated. Colonel Harris

ain contention was that a much greater amount treatment must be carried out than at present by e practitioners who discovered the syphilis in the st instance ; the women had confidence in their own ctor, whereas V.D. specialists were unknown to them.

Discussion.

Dr. A. C. ROXBURGH gave some figures from a small tenatal clinic in Battersea with which he had been nnected for some years. As a result of the treatment syphilitic pregnant women during the period of station, the proportion of positive Wassermanns nong them had steadily diminished. In 1924 it as 3·5 per cent., in 1925 2·1, in 1926 it had fallen to 5. Of 41 syphilitic women so treated only three owed any outward evidence of syphilis, so that the agnosis had to rest entirely on the result of the assermann test. The treatment he carried out was weekly injection of N.A.B. for eight weeks, con-nuing thereafter fortnightly, to the accompaniment mercury pills throughout.

Dr. T. ANWYL-DAVIES submitted a series of atistics of cases of syphilitic expectant mothers ated at the V.D clinic at St. Thomas's Hospital. efore antenatal treatment was established, of 9 pregnancies 50 per cent. produced children who re unhealthy. 300 syphilitic expectant mothers re put on to treatment and only 9 per cent. of the spring were unhealthy. Even one course of treat-ent greatly reduced the severity of infection in the ild. He firmly believed that if once a woman came syphilitic she was liable at every subsequent egnancy to produce a syphilitic child. The old idea at the treatment increased the risk of post-partum emorrhage had been shown to be a myth. At St. omas's, where the department had its own lying-in rd, there had been no instance of post-partum emorrhage in eight years.

Dr. DOROTHY LOGAN said that once she saw good ason for putting a woman upon antisyphilitic eatment she did not discontinue or modify it cause of pregnancy. Usually she was content to ve seven injections of N.A.B., but mercury was ntinued much longer, and potassium iodide was ven in gradually increasing doses.

Dr. MARGARET RORKE said the average amount treatment given to pregnant syphilitic women before 20 was inadequate. In her view the ideal means of eatment was a combination of 914 with mercury. casionally a woman could not tolerate arsenic, and those cases bismuth was substituted. In her clinic amination of the urine was made before each jection, and if there was an indication of toxæmia ermediate treatment was carried on for a time. re treatment and a longer period of supervision uld be needed before she could be satisfied that r work would stand inspection in 15 years' time.

Dr. F. FOWLER WARD had also noticed that at bsequent pregnancies syphilitic mothers often gave th to healthy infants. Yet his practice was to duce all syphilitic mothers to receive treatment at ch pregnancy. In those who had had syphilis for me years he could seldom obtain a negative assermann.

Dr. DENNIS VINRACE did not see the need for acing pregnant syphilitic women in a separate tegory. He did not think that compulsory notifica-n of pregnancy would be acceptable.

Dr. T. J. WRIGHT spoke of the preference of some actitioners for the intramuscular and deep sub-taneous methods of giving the arsenical prepara-ns, as they were supposed to be better than the travenous method.

Reply.

Colonel HARRISON replied that during the war bcutaneous injection was found to be more effective an intravenous ; it was 12 per cent. better in parate series of 200 cases.

Dr. NABARRO, in reply, said he considered that ramuscular treatment often gave better results an intravenous, both in adults and in congenital philis in children. But the intravenous was the less painful, and it was not uncommon for patients, especially young ones, to complain of pain at the site of the intramuscular injection on returning home. It would be generally agreed that the Wassermann being positive meant the presence of living spiro-chætes in the body, though whether they were necessarily causing harm was open to question. He agreed it would be very difficult to bring about notification of pregnancy, whatever good practical results might be expected from it, as mothers would be naturally diffident about proclaiming the fact. The great difficulty in this matter lay in following up the cases. Some of the obstacles in the way of bringing patients to the hospital again were real ones, as in cases of poor people living 20 miles in the country ; also, a woman advanced in pregnancy shrank, as a rule, from being much in public.

TUBERCULOSIS SOCIETY.

AT a meeting of this Society held on Jan. 20th there was a discussion on the

Work and Aims of Tuberculosis Care Committees and Kindred Agencies.

Dr. GEORGE JESSEL said that he had been actively concerned in the establishment of nine care committees and in the administration of other forms of public assistance. Since the first committee of this kind in Lancashire was established in 1913 their scope and function had become narrower, many of their activities having become part of the ordinary dispensary routine. The work of dispensary medical officers and nurses was in itself a most important form of care work, including as it did sympathetic instruction and encouragement of patients and their families, as well as the provision of many necessary articles, such as sputum flasks. In spite of the numerous other public sources of assistance available for poor consumptives and their families, he thought there remained a good deal of scope for the activities of care organisations. If, however, these were to be really efficient, they must have accurate information both about the medical condition of the patient and about his social and financial circumstances. This information it was the function of the tuberculosis officer and of the tuberculosis health visitor to supply, and the dispensary should be the centre of all care activity, in order to ensure proper coördination of the help given to each family.

Dr. Jessel's own area had a population of 339,704, of whom, at the beginning of 1927, 1908 were under dispensary supervision. The Lancashire care committees included representatives of district councils, boards of guardians, trade-union organisations, employers' organisations, local health officials, and other individuals known to be interested in social work. Theoretically it was not difficult to secure a membership which was nominally representative, but in practice it was not always possible to maintain its representative character, one great hindrance being the dominance of one political party, which resulted in keeping away those of opposite views. Care committees were better without advanced politicians.

The existence of care committees, he thought, relieved the tuberculosis officer of the responsibility of acting as a relieving officer, and while the tuberculosis officer must keep in constant touch to prevent the committee from running off the rails for want of proper guidance, yet the committee must be made to realise that it was ultimately responsible for its decisions. The committees acted also as educational centres, and in many cases they had organised lectures by the tuberculosis officer, thus assisting in the larger campaign against the disease. One of the avowed objects of the work was to give temporary assistance and to prevent patients and their families from becoming chargeable to the local board of guardians, which was economically unsound, apart from questions of sentiment. If the assistance required was very great, the case might have to be referred to the

relieving officer. It was not well enough known that a poor-law medical officer might sanction extra nourishment to the sick poor. Among the more valuable ways in which help was provided by care committees was the loan of bedsteads and mattresses. Sleeping arrangements in infectious cases had steadily improved within the last ten years, in spite of the overcrowding. The most difficult problem was to find work for patients, especially now that trade was so bad; a patient must usually be fit in order to do a full day's work regularly. Figures for Dr. Jessel's own area last September showed that of 526 pulmonary patients under active medical supervision by the tuberculosis officer, 248 were unfit for work, 208 were working, and 70 (13 per cent.) were out of work although considered fit for it. It was wise, if possible, to place patients in occupations bearing some relationship to those with which they were familiar. As a rule, what mattered most was not the job but the conditions under which it was done.

Dr. A. P. FORD pointed out that the work of a care committee in a county area necessarily differed in many respects from that of a large city or town. The patient to be cared for should be known personally to those trying to help him, and this object could not be attained by the creation of one committee for the whole county. The difficulty had been met in Hertfordshire by the appointment of one or more influential persons in various urban and rural localities who were willing to undertake the work, while the only after-care committee functioned in the largest borough of the county. It was much easier to get things done promptly when one individual was responsible than when the matter had to be referred to a committee. Dealing with the duties of a care committee or care worker, Dr. Ford said that while it was a great advantage to have a small fund at their disposal, he thought that this fund should not be used for providing nourishment or necessities. Such provision was the duty of the board of guardians or the local authority. It was usually easy in these days to persuade a patient to apply for assistance from the relieving officer, and it was to be hoped that as a result of impending changes in the legislation regarding boards of guardians, the system of granting outdoor relief to sick persons unable to follow their occupation would be so simplified that every genuine case would receive adequate and immediate assistance. With regard to tuberculous patients, however, much closer coöperation would be necessary between the relieving officer and the tuberculosis officer if this object was to be attained. The fund at the disposal of the care workers could be used to great advantage in providing extra clothing for patients, assisting to pay for domestic helps, in paying for structural alterations to improve unsuitable home conditions, and in many other ways which would not come under the functions of the board of guardians, such as rendering assistance to the family when the mother developed tuberculosis. Care workers visiting the homes of tuberculous patients should be careful not to take on the function of the official health visitor, such as the search for contacts, which was part of the duties of an officer who had been trained in such work. Discussing the question of employment of ex-sanatorium patients, Dr. Ford said that mothers of families provided the most difficult problem of all, and it was with this class of patient that the assistance of the care worker was most urgently needed. The work of a housewife with a young family was probably the most unsuitable occupation for a tuberculous patient. He did not recollect any case of arrest of the disease in a mother of a working-class family, with tubercle bacilli in her sputum, who had to return to the care of her household on discharge from the sanatorium. Drugs and extra nourishment were of no avail unless some arrangement could be made whereby the mother was relieved of the majority of her duties and worries. With regard to ex-Service men, Dr. Ford said that he had never come across a pensioner who had been able to earn an adequate living, outside an institution, by means of a new occupation he had been taught as a result of a st of 12 months or so at one of the various traini colonies.

Miss K. LEWIS (Public Health Department, L.C. contributed a paper, read in her absence Dr. G. T. HEBERT, on the work and aims of tuberc losis care committees in London. There were, s said, 26 borough care committees, most of which w doing useful and constructive work, up to the standa desired by the London County Council. In th other boroughs the functions of the care committ were performed by a health worker or almon The L.C.C. had laid down a scheme for the guidan of care committees, and Miss Lewis discussed t with special reference both to the ways in which t committee should receive its information abo patients and the kind of assistance which it co provide. The arrangements about assessments residential treatment were also gone into. No co tribution was assessed in respect of any insur person whose income was the main support of t family and would be sensibly reduced while he w undergoing treatment, or in the case of an ex-Serv man in respect of whom the Ministry of Pensio defrayed the cost of treatment. In the case of childr a small contribution, roughly equivalent to the c of maintenance of the child at home, was assessed the circumstances appeared to justify the dema In no case, however, was the provision of treatm delayed until an assessment had been made.

A recent departure, said Miss Lewis, which mig in time come to rank as one of the most import duties of the care committees, was the organisati and management of handicraft classes. These class which entailed no expense to the dispensary servi were intended for patients discharged from sa toriums after treatment who were anxious to t up work but were physically unfit to compete in t labour market. The value of the work lay rather providing the patients with a new interest a occupation than as a means of earning money, b the proceeds of the sale of the articles covered least the cost of production. Three such classes h been started successfully, two more were beginni this month, and four were in process of organisatio

Discussion.

Dr. S. VERE PEARSON said that the main probl was economic. He agreed that the housewife was most difficult type of patient to deal with, and t was true not only of the insured class but also middle-class patients.

Dr. N. DONNELLY thought that two of the m useful ways in which care committees could help v in the supply of home helps, and in the boarding of children from infected homes.

Dr. G. MACDONALD wished to stress two poi First, that the person who dealt with the care co mittee should be the secretary of the dispensary a should be a paid official. No case ought to co before the care committee without the knowledge the tuberculosis officer. Secondly, there ought to more coöperation between tuberculosis officers and heads of hospitals. It was better if the communi tion could be direct. He thought the care co mittee ought not to have control of large funds, should have a small fund for emergencies.

Other speakers referred to the great help receiv from the Charity Organisation Society and Invalid Children's Aid Association, through wh much of the work of the care committees in cert areas was carried on. One or two speakers thou care committees were unnecessary, at least in ru areas, where the work could be better done by tuber losis officers and their assistants. A care commit would only duplicate the work, and it was sugges that the Ministry of Health should not be encoura to press these committees on all districts, irrespect of the local conditions.

MEDICO-LEGAL SOCIETY.

At a meeting of this Society held on Jan. 26th ir WILLIAM WILLCOX, the President, took the chair, nd Mr. F. LLEWELLYN-JONES read a paper on

)RUNKENNESS AND CIVIL AND CRIMINAL RESPONSIBILITY: A STUDY IN COMPARATIVE LAW.

[e reviewed the laws relating to civil and criminal esponsibility of intoxicated persons in different ountries, most of which corresponded with the nglish custom, as summarised in Lord Halsbury's Laws of England." The Code Napoléon had no ecific reference to the civil problem, but French urts had arrived at decisions which regarded the ery drunken man as insane; they had, however, ccepted no lesser state of inebriation as a reason for lieving him from his contract, unless the other party ad resorted to fraudulent devices to make him drunk. greements entered into in taverns might be annulled ithin 24 hours in France, and in Holland and Flanders ey were regarded as invalid unless ratified within 4 hours. Recent Austrian and German legislation ad enacted that if a man were made drunk through ickery, so that a wrong resulted, then the third party ho had made him drunk should be liable to the jured person.

Criminal Responsibility.

In the matter of criminal responsibility different ystems showed considerable divergence. The most portant case in English law was that of the Director Public Prosecutions *v.* Beard, which had come before e House of Lords in 1920. Lord Birkenhead, livering judgment, had referred to a sixteenth ntury ruling which said that if a person drunk kills nother he shall be hanged for it; inasmuch as that ndition arose from his own act and folly he shall ot be privileged thereby. Hook and Blackstone in e two succeeding centuries had ratified this, but dicial decrees since the early nineteenth century owed that the rigidity of the rule had been gradually laxed. Lord Birkenhead had pointed out that the w took no heed of the cause of insanity; if alcohol used insanity in the legal sense then the patient had complete an answer to a charge as the sufferer from y other form of insanity, however temporary his ndition. Drunkenness, however, was no defence nless there was evidence that the accused was so unk that he was incapable of forming the specific tent necessary to the committal of a crime. If the idence merely established that his mind was so fected by drink that he gave way the more readily an impulse, then that would not rebut the assumption that he intended the consequences of his act. n Australian court had recently quashed a conviction, lding that there was no animus gerendi, since the cused had been too drunk to know what he was ing.

The Indian Penal Code differed from English law that the man drunk through his own fault was no tter off than the sober man. The laws of the nited States corresponded more or less closely with e principles laid down in the case of Beard. Before e French Penal Code was drawn up drunkenness had tually been regarded as an aggravation of an offence, d the man had been punished for two evils—the use and the result. For a long time in France unkenness could not be pleaded as excuse or in itigation of an offence, but milder views had adually gained ground. The German Code classified unkenness in two ways: first the circumstances der which the person became drunk—i.e., voluntrily; fraudulently, making himself intoxicated in der to facilitate a crime; or accidentally, due to the ickery of another party. Secondly, it recognised ages of drunkenness; first where the continuity consciousness was retained; secondly, where nsciousness remained but the mind was so clouded at mistakes were committed; and thirdly, complete toxication depriving a man of his reason. In the st stage he was always responsible for his acts; the second stage was rarely free from imputability, and then only if he were "accidentally" drunk. In the third stage he was hardly every held responsible. Intoxication might be urged in mitigation if it were accidental or voluntary. In Hungary a man might be acquitted if "dead" drunk, or might plead it in mitigation if his intoxication were less complete. If he had taken drink to nerve himself for his crime it was regarded as an aggravation of the offence. Swiss law was much the same as German, but in Italy alone of any country was the chronic alcoholic sent to serve his sentence in a special establishment where he was treated for his condition. Drunkenness under the new Italian Code was neither to aggravate nor extenuate an offence, save in the case of drink taken to facilitate a crime or "accidental" intoxication. If a man made another drunk in order that he should commit a crime, the first man was to be punished in place of the delinquent.

The Drunken Motor-driver.

Nowadays few cases caused such difficulty as that of the drunken motorist. No definition of drunkenness had been given. The American Motor Vehicles Act, 1921, had gone a little further than English Law in stating that a vehicle driver was drunk if he were so much under the influence of intoxicating liquor as to be incapable of exercising effective control of such vehicle. Judge Sturges last year, at Windsor, had defined it as a condition where the skill and judgment normally required in manipulating a motor-car were obviously impaired as the direct result of alcohol.

Discussion.

Sir WILLIAM COLLINS said that there could be no definition; drunkenness was a matter of degree. It was comparable to the problem of when a calf became a cow, or a small heap a large heap. Witnesses should not be pressed for definition, called by John Hunter "of all things the most damnable."

Mr. ROLAND BURROWS said that the tort committed while in drink was a sphere wherein the theory of the law was wholly unworked out, as was also the case of insanity. While an insane person was certainly liable for some of his torts, it was quite impossible to pronounce upon others. A numbers of torts did not depend on a state of mind at all, and for these drunkenness ought not to affect liability. Criminal responsibility had been worked out at much greater length. There was reason to believe that, if the jury had been asked whether or not Beard had been drunk at the time of his offence, the answer would have been No. The judgment of Lord Birkenhead on this case had been the considered opinion of the House of Lords.

Mr. J. P. VALETTA wondered why some of the tests applied by doctors to persons accused of drunkenness did not seem to appeal to juries, although they impressed magistrates. He pointed out that a doctor was dragged out of bed at 3 A.M. to test a man at a time when even the most sober might not walk just as the doctor wished. Such tests ought not to be conclusive. The burden of establishing a standard of test rested on the medical profession, and he urged a reconsideration of the subject.

Mr. ROMAIN said that the law had deliberately avoided definition of drunkenness because it recognised different degrees. Before motor-cars became common the matter had hardly ever come before the courts.

Dr. MORGAN FINUCANE maintained that medical men had made real progress in this matter and cited Dr. Godfrey Carter's work on urine analysis. In his opinion no man who drank alcohol ought to drive a car.

Mr. W. A. CHADWICK quoted two definitions of drunkenness. The first was the military one; if a drunken man was fit to do his job, then he was sober enough to do it. The second had been given him by his grandfather: "not drunk is he who from the floor can rise again and still drink more, but drunk is he who prostrate lies without the power to drink or rise."

Mr. R. BOLTON spoke of the individual differences in drunkenness. An experienced driver might have lost his road sense, but still be better than an unskilled driver sober, and the two were equally guilty for being on the road at all.

CAMBRIDGE MEDICAL SOCIETY.

A CLINICAL and pathological meeting of this Society was held on Jan. 13th at Addenbrooke's Hospital. Dr. H. B. RODERICK, the newly elected President, took the chair.

Treatment of Varicose Veins by Injection.

Dr. F. A. HEPWORTH (Saffron Walden) described his experience of the treatment of varicose veins by the injection of a solution of sodium salicylate into the veins. The advantages of this method, he said, were that it could be used without difficulty in private practice, that the apparatus was very simple, and that the patients were able to continue their work during treatment and did not have to lie up at all. He used the following apparatus: a glass syringe with an eccentric nozzle to fit a short, fine needle, two sterile solutions of 20 and 30 per cent. sodium salicylate, and iodine and swabs for cleansing the skin over the veins. His method was as follows. The patient sits on a high couch, with the legs hanging over the edge, the skin over the most prominent veins is swabbed with iodine, and the needle is inserted obliquely into the chosen vein; a small amount of blood is withdrawn into the syringe before injecting the salicylate solution so as to ensure that the needle is in the lumen of the vein; 2 c.cm. of the solution are then injected slowly and the needle withdrawn. Dr. Hepworth said that he was accustomed to inject patients once a week, doing four veins at a sitting. He used the 20 per cent. solution the first time and the 30 per cent. subsequently. He emphasised the importance of injecting the solution into the vein, any leak into the surrounding tissues being liable to cause severe pain and ulceration, which would only heal with difficulty. The treatment should not be given if there was evidence of thrombosis of the deep veins of the leg. If it was properly carried out a slight tingling was the only sensation felt by the patient, who might be allowed to walk out of the house five minutes later. He showed two patients as examples of those he had treated and cured of symptoms by this method.

The PRESIDENT said that he had not tried injections for varicose veins, but in the treatment of hæmorrhoids he had used injections of urethane and quinine with success. This method was specially valuable when insufficiency of hospital beds prevented a more radical cure.

Dr. W. G. NASH (Bedford) had treated six cases of varicose veins with injections of quinine and urethane; no pain or discomfort had been caused, and the results were very satisfactory.

Demonstrations and Cases.

The PRESIDENT showed three pathological kidneys which he had recently removed. One was that of a man aged 60, who suddenly developed profuse but painless hæmaturia, which persisted for a week. A radiogram showed a faint shadow in a very large kidney, which on account of the continual hæmorrhage was removed. It proved to be a classical example of polycystic disease of the kidney with a concretion in the substance of the lower pole which had been shown by a faint shadow in the X ray. The patient had no symptoms after convalescence.

Dr. G. S. HAYNES showed a child on whom Mr. W. H. Bowen had performed Rammstedt's operation for congenital pyloric obstruction ten months previously. The child was in good health and weighed 25 lb.

Dr. FFRANGCON ROBERTS showed a radiogram of the skull of a patient in whom right facial paralysis had developed after a blow on the head, caused by a fall on wet leaves. The lateral view showed a horizontal crack involving the squamous and petrous portions of the temporal bone. A second radiogram, taken from above, behind and slightly to the left, to show the inner petrous bone, showed a second crack leading from the first down to t stylo-mastoid foramen.

Mr. W. H. BOWEN said that an interesting poi about the case was that the man only sought medic advice 19 days after the accident, and then only f the facial paresis, for he had had no other symptom

Dr. C. H. WHITTLE showed the heart and aor of a man of 20, who had died suddenly while ridi a bicycle. There had been no premonitory symptor or previous history of over-exertion. The hea which weighed 24 oz., showed enormous muscul hypertrophy, especially in the walls of the ventricl Microscopically the muscle appeared quite health The only other abnormalities in the body were a ve slight decrease from normal in the lumen of t aorta, and a thymus, which weighed 28 g. D Whittle said a number of such cases had been describe chiefly in America, but nothing was known as to t true cause of the condition or the reason for deat He also showed a specimen of a liver taken from child who died at the age of 5 months as a result congenital absence of the gall-bladder.

Dr. J. R. C. CANNEY described a case of acromega of which Dr. Roberts showed radiograms; Mr. Bow showed a case of spina bifida; Mr. A. S. H. WALFO demonstrated epithelioma of tonsil and gumma the turbinate bone; and Dr. W. R. GROVE (St. Iv showed a heart with gummatous pericarditis.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH.

A MEETING of this Society was held on Jan. 18t when Dr. A. LOGAN TURNER, the President, took t chair, and Dr. CHALMERS WATSON read a paper on

Unrecognised Toxic Substances in Human Fæces.

This paper was published in THE LANCET of Jan. 28 (p. 174) and included the results of experiments Dr. P. De on the effect of injecting into cats a seri of extracts from human and animal fæces. T following is a summary of the discussion which followe

Prof. A. J. CLARK said he had followed the expe ments with interest. The bowel was the "unkno continent" of the body, and its pathology had be less explored than that of other organs. The liv was not the perfect guardian to absorption that it w supposed to be; it often failed to defend the bo against toxic substances, and a small difference the material might make an enormous difference absorption. It was wrong to assume that because one particular kind of intestine toxins did no har they did not do so in others. Our knowledge of t liver, said Prof. Clark, was absurdly scant, and it w very necessary that more work should be done absorption from the colon and its influence on disea

Prof. G. M. ROBERTSON thought it very difficult say, from the clinical point of view, to what extent t symptoms of mental diseases were due to intestin toxæmia and to what extent the disturbances of t intestines were a sequel to mental disorder. He h often questioned intelligent patients as to whetl their mental disorder—e.g., melancholia—or th gastro-intestinal condition had come first. Most them believed that the mental symptoms preceded t intestinal. This might easily be accounted for by t melancholic state, with its loss of appetite a digestive interest in general, causing retardation alimentary movement with consequent constipati and putrefaction.

Dr. STANLEY DAVIDSON laid stress on the importa of the hydrogen-ion concentration in the bow especially in cases of pernicious anæmia, wh intestinal bacteria were more numerous than any other condition he had seen. Team-work w essential if the subject was to be considered from points of view.

Dr. A. GOODALL and Dr. R. A. FLEMING also to part in the discussion.

Dr. WATSON, in reply, referred to Dr. Davidso remarks on the necessity for team-work, and remark

hat in the recent monograph on Toxæmia of Pregnancy ublished by the Medical Research Council there were 20 pages discussing 200 cases and 40 controls, yet nly three lines were devoted to auto-infection and bout 15 to auto-intoxication. No mention was made f the condition of the urine or stools along the lines) which he had referred.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION OF MEDICINE.

AT a meeting of this Section held on Jan. 20th,)r. G. E. NESBITT, the President, in the chair, a paper ntitled

The Sensitive Child

'as read by Dr. B. D. CRICHTON, who pointed out that very sensitive disposition might produce syndromes apable of being mistaken for the symptoms of disease. Iuch depended on the wisdom of those in charge of ich children, for abnormal behaviour in a sensitive hild was often due to the follies or neuroses of the arent or nurse. Sympathetic handling was essential, nd encouragement rather than repression was the lue to managing most of the problems of difficult hildren. Many children laboured under the disdvantage of being forced to attend a school where ducation was carried out in surroundings and under onditions which were prejudicial to good health, nd Dr. Crichton urged that medical men in Dublin hould unite to make educational authorities see the arm done by the present system. In the Dublin chools the working hours were long, the lunch interval 'as badly chosen, lavatory accommodation was efective, and medical inspection wanting.

Dr. M. F. O'HEA agreed that the sensitive child 'as a definite entity. He felt that to try to make hildren plucky by holding up to them the pluck of ther children was a great mistake. The best time or the principal meal was at present a vexed question ; ome schools insisted that the children should have inner at 1 o'clock, and stopped school from 1 to 2 or this purpose. This he thought bad for the hildren's digestion, as it meant that they had to eat heir meal too hurriedly.

Dr. V. M. SYNGE considered that children went to chool far too young and learnt too many things by outine instead of reasoning them out. The so-called ncrease of education in Ireland by compulsory ttendance at the national schools was not an unmixed lessing. He had seen children in quite an advanced tage of tuberculosis who were sent to school every ay, as their parents were afraid of being fined if they id not send them. The national schools were far too rowded ; in many of them there were 150 children n about three rooms, with only three teachers.

Dr. N. FALKINER asked if most of the children seen y Dr. Crichton had had some definite organic lesion ; ad their diet been faulty, and had the majority of hem been breast-fed ? If undue sensitiveness was ssociated with artificial feeding it should be more ommon in private practice than at hospital.

Dr. R. J. ROWLETTE, referring to the necessity for n altered school hygiene, said it was a pity that the nforcement of attendance at schools should have nticipated the establishment of a proper system of edical inspection. Whilst individual attention was ecessary for the diagnosis of the sensitive child's ondition, he thought it might be carried too far in reatment. If individual attention was unduly ressed it might lead to the child concentrating on self, which was unhealthy.

Dr. LEONARD ABRAHAMSON agreed with Dr. richton that one of the greatest difficulties in ealing with the nervous child was the comparatively nknown factor represented by the nurse who was nterposed between parents and child. In some cases was as necessary to study the parents and the nurse s it was to understand the child. School hours were ertainly too long, and he thought it unfair that the ours should be longer in national schools than in rivate schools.

The PRESIDENT said he could not imagine anything worse than a child who was *not* sensitive, or an adult either. He thought Dr. Crichton should have called his paper The Supersensitive Child. Undoubtedly one of the most important influences in the bringing-up of children was the nurse ; another important factor was heredity, which played a great part in the sensitiveness of children. Nowadays, in cases of extreme naughtiness, the question of encephalitis lethargica was worth considering, for children who had suffered from this disease, even slightly, were liable for some time afterwards to be naughty purposely.

Mr. W. C. MCFETRIDGE and Sir JOHN MOORE also joined in the discussion.

Dr. CRICHTON, in reply, said that when talking about sensitive children he had really meant super-sensitive children. The average child wanted to be constantly doing something, and he thought that care should be taken to study its favourite pastimes and habits. The education of nurses for small children had not really been given enough thought. It must be borne in mind, however, that nurses were rather born than made. The child's heredity was exceedingly important, but it was equally difficult to tell the parents the trouble. He believed that not enough interest was taken in the teaching of children ; the preparatory school was more important even than the public school, as in the first five years a boy could be either made or marred. He had not found much difference between breast-fed and bottle-fed children. By overtreatment a child could, of course, be made more sensitive. He thought that the principal meal should be between 1 and 1.30 o'clock, and not as late as 2 or 3. The interval allowed at most schools in the middle of the morning was too short.

Dr. J. H. POLLOCK read a paper entitled

A Case of Psychoneurosis.

In describing the clinical history in psychoneurosis it was important, he said, to pay attention to the time-factor. In the case he reported the psychical disturbances came on first some considerable time after the shock to which they were due, and aroused buried fears dating back to a much earlier period. It was also important to remember that recovery was bound to be slow, and attempts to hurry the process were comparable to "meddlesome midwifery." Simple analysis might help the physician to understand the details of his case, but it was a grave mistake to interest the patient in the process or present it to him as a means of treatment. The psychoneurotic tended to be subjectively-minded, and the aim of treatment should be to make him objectively-minded.

The PRESIDENT, after pointing out that repression was now admitted to be one of the most important factors in mental upset, went on to discuss the endocrine basis of these disturbances. More attention should be given to the relation of psychoneurosis to the ductless glands.

Dr. ABRAHAMSON considered that cases of psychoneurosis could only be investigated with difficul y in general practice and should not be dealt with except by a man who had time to go into them thoroughly. He referred to a mental patient whom he had recently seen. She had had a motor accident, had fractured her skull, and had been trephined ; shortly afterwards she was certified as definitely insane. In conversation the patient constantly spoke of numbers and also of colours, and Dr. Abrahamson had ascertained that just before the accident her eyesight had been tested, and she was being attended by nuns who wore black and white.

Dr. ROWLETTE said that in these cases what was most important was not classification in regard to treatment, but in regard to prognosis. The question was when should the line of certification be drawn ? Many of these patients became seriously depressed, and it was in the depressed patient who was not actually insane that there was the greatest danger of suicide. The condition often arose out of a long-standing conflict, generally between one of the primal motives in human beings on the one hand and moral

restraint on the other. People often took refuge in drugs as a method of preventing loss of self-control. In all these conditions both the mental and the physical substructure had to be considered, and it was impossible in any case to separate one from the other completely.

Dr. O'HEA thought that cases of severe neurasthenia were not nearly so common now as in the previous decade. Dr. T. M. CORBET, Dr. R. H. MICKS, and Dr. R. S. STEEN also spoke, and Dr. POLLOCK replied.

A Case of Bronchiectasis.

Dr. ABRAHAMSON showed a child aged 4 with fibrosis of the left lung and left-sided bronchiectasis.

The patient had been seen by him for the first time on June 15th, 1927, and the only history was one of recurrent attacks of cough with sputum. Examination showed some cyanosis of lips and cheeks and clubbing of the fingers. There was diffuse dullness over the left axilla and over the back of the left lung, whilst towards the base there was an area yielding signs of a cavity. A diagnosis of bronchiectasis was made and the patient was admitted to hospital. There it was noted that the cough occurred mainly in paroxysms, and that the sputum was fœtid. Vomiting followed some of the paroxysms. Radiography showed that the inner half of the left pulmonary field was obscured by a dense, almost homogeneous, shadow. Some comparatively translucent areas suggested cavitation. The outer half of the lung had a network of dense shadows, and the cardiac arteries were completely obscured. The radiographic appearances pointed to the presence of large bronchiectatic cavities, with extensive fibrosis. Radiograms were also taken after injection of lipiodol. The sputum was negative for tubercle bacilli, and culture yielded streptococci and pneumococci. Treatment was by creosote and vaccine, with tonics, and considerable improvement had taken place.

The PRESIDENT said that these cases caused a great deal of worry because they were usually shrouded in mystery, and it was exceedingly difficult to give a prognosis. He himself had an almost exactly similar case under his care.

The patient was a girl, aged 9, who began to run a high evening temperature ten days after having had tonsils and adenoids removed. She had now been in hospital for a couple of months. There was a definite area of dullness at the apex of the right lung, and a radiogram showed a dense shadow and a cavity containing fluid. The sputum had been examined several times with negative results. After a time the patient brought up a lot of foul sputum and got better for a week, but then relapsed again. A little later, however, she brought up pus and a lump of solid material, the size of a hen's egg. This turned out to be a blood-clot. Dr. Nesbitt thought that after this the girl would die, but next day there were obvious signs of a cavity and cavernous breathing. It was obvious that the girl had an abscess in the lung, and he thought that this must be caused by a foreign body.

The President said that this was the second case which had come under his care with a definite abscess of the lung, following the removal of tonsils and adenoids.

Dr. W. M. CROFTON referred to treatment by immunisation. In these cases tubercle bacilli were always looked for, but the possibility of any other organisms being present was usually overlooked.

Dr. ABRAHAMSON, in reply, said that as there was no history of an acute infection and no suggestion of inhalation of a foreign body he considered that the bronchiectasis was due to congenital weakness of the left bronchial tree in association with recurrent bronchitis. Thoracoplasty had been considered, but in view of the improvement was not contemplated at present. He was of opinion that in this case vaccines had been of material help.

DONCASTER ROYAL INFIRMARY.—Serious money difficulties have put a stop to the erection of the new building, which is intended to contain 300 beds. In October, 1926, the Prince of Wales laid the foundation-stone of the first three wards, which will contain 140 beds, but the depression in trade following the coal strike stopped the flow of money, and for more than a year the foundations have remained untouched. The infirmary is now so overcrowded that several patients are lying on mattresses on the floor, while some of the cots contain two children.

Reviews and Notices of Books

THE INFANCY OF MEDICINE.

By DAN MCKENZIE, M.D. Glasg., F.R.C.S.I., F.S.A. London: Macmillan and Co. 192[illegible]. Pp. 421. 15*s*.

THIS inquiry into the influence of folklore upon t[illegible] evolution of scientific medicine is, as might be expect[illegible] from its author, alike full of information and pleasa[illegible] writing. Dr. McKenzie expressly disclaims havi[illegible] written a history of medicine; rather he is describi[illegible] medical art in the making—"the shifting sands[illegible] in his own words, "of medical opinion and modes [illegible] thought as well as the record of outward and visi[illegible] happenings." The long and complex subject [illegible] treated in six stages—namely, the prehistor[illegible] including the savage epoch; the ancient epoch, whi[illegible] takes note of Egyptian, Babylonian, Persian, Buddh[illegible] medicine, and occasionally of ancient Chinese a[illegible] Japanese science; the classical epoch, covering Gre[illegible] Roman, and Arabian medicine; the mediæval epo[illegible] where the reference is to the Dark Ages and the Mid[illegible] Ages; a fifth epoch, termed pre-scientific or transition[illegible] bringing us to the beginning of the nineteenth centu[illegible] since which date all that happened is summarised [illegible] the scientific or modern epoch. In his preface [illegible] McKenzie apologises for these divisions as arbitra[illegible] but while it is true that they are not separated fr[illegible] one another by any clear line of demarcation they ma[illegible] an extremely convenient scheme for dealing coheren[illegible] with big and heterogeneous material.

Concerning the early evolution of the medical ma[illegible] which implies the separation of medicine from mys[illegible] cism, Dr. McKenzie writes on familiar lines—h[illegible] could it be otherwise? But the chapters on primiti[illegible] pathology and treatment will reveal to many read[illegible] who have no first-hand acquaintance with ethnolo[illegible] or its literature what were man's starting conceptio[illegible] of disease and what the parts played by belief [illegible] demoniac possession and magic, both of which t[illegible] author conceives to have had more influence th[illegible] any appreciation of natural causes. These sectio[illegible] constitute the first part of the book, and a glance at t[illegible] full and careful bibliography will show how well do[illegible] mented the author is and should help readers [illegible] follow in his footsteps.

In the second part individual methods of treatme[illegible] are taken up, the origin and history of various cree[illegible] and the employment of various drugs being discuss[illegible] the statements being again supported by voluminc[illegible] references. It should be useful that the author h[illegible] here attempted to follow up the ancient theories a[illegible] technique so as to correlate modern medical thoug[illegible] with the origins, many and curious, from which it h[illegible] evolved. But in respect of the evolution of anim[illegible] remedies the various revolting devices for relief a[illegible] cure which are described show how entirely t[illegible] intentions as well as the procedure of our forefath[illegible] were divorced from the researches that have led up [illegible] the recent introduction of animal products into c[illegible] therapeutics. Our laboratories owe nothing to th[illegible] coarse superstitions, and Dr. McKenzie issues [illegible] warning to this effect which is timely, for we [illegible] in the popular press the exact reverse stated, time a[illegible] again, in order to frame an argument against t[illegible] existence of medical progress. The evolution [illegible] botanical remedies, the influence of astrology [illegible] medicine, the history of balneology, and mu[illegible] piquant writing on superstitions in connexion wi[illegible] menstruation, impregnation, circumcision, and oth[illegible] mutilations, lead up to the stories of early operati[illegible] surgery, and of the practice of midwifery through t[illegible] ages. Thus Dr. McKenzie has made up a volume [illegible] absorbing interest to the historical student, while a[illegible] supplying information which is often exactly apt [illegible] the understanding of medical literature to-day.

The book is dedicated to the honour and glory [illegible] the author's Alma Mater, the University of Glasgo[illegible] for it constitutes the Prize Essay in the History [illegible] Medicine awarded in 1925 by that University.

YORRHŒA ALVEOLARIS.

By F. ST. J. STEADMAN, D.P.H., L.R.C.P., M.R.C.S., L.D.S., Dental Surgeon to the Royal Dental Hospital and West London Hospital. London: Henry Kimpton. 1927. Pp. 263. 25*s*.

THE term pyorrhœa alveolaris is admittedly a isleading and inaccurate one. But since there is name which correctly describes the salient features the various conditions to which this name is plied, few can complain of its use as a convenient le for those diseases which affect the gum and riodontal membrane. This book includes ætiology, thology, symptoms, sequelæ, and treatment. Mr. eadman recognises three types of pyorrhœa, the rm carbohydrate-stagnation type, the atrophic pe, and ulcerative gingivitis. We doubt if the clusion of this last condition is legitimate. It is acute condition, of specific causation, and if ated, of brief duration. Clinically and ætiologically is entirely different from the chronic conditions noted by the term pyorrhœa. Mr. Steadman vs great stress on the rôle of carbohydrate stagnan in causing a marginal gingivitis, which may later d to definite infection of the periodontal membrane. at this may be one of the factors concerned seems obable, but the author surely makes too much of

When he says that pyorrhœa is essentially a ease of childhood, apparently on the grounds that ngivitis is common in childhood, we cannot follow n. Not every case of gingivitis develops into pyorœa and it is not universally accepted that pyorrhœa vays begins as a marginal gingivitis. Mr. Steadman ers but little explanation as to the causes of the ophic type. Injury, blood-borne infection, and umatic occlusion are mentioned, but it is obvious at the ætiology of this condition is obscure. The apter on pathology is disappointing. There is mention of the work of B. Gottlieb, and the earches of H. K. Box do not receive adequate tice. The changes in the pulp which almost ariably accompany periodontal disease are not scribed. The few pages of physical signs and mptoms are equally meagre. The account of bacteriology of pyorrhœa is better, but even e the important work of J. Kritchevsky and Séguin on the possible rôle of *B. fusiformis* d *S. vincenti* in pyorrhœa is ignored. The largest tion in the book is devoted to the systemic comcations which may follow from dental sepsis. . Steadman casts his net widely and includes most every disease which at one time or another s been related to pyorrhœa, on the grounds of its provement following the treatment of the teeth. adopts the rather unusual proceeding of giving brief account of the symptoms of many of these eases. This increases the size of the book, which a disadvantage, and, moreover, may give the dent the fallacious impression that insanity, rthema nodosum, cancer, asthma, glycosuria, and forth are specifically due to dental sepsis, though is is certainly not the author's aim. The section treatment is detailed and embodies many useful nts. It is the best part of a book which, in spite its defects, contains many shrewd reflections and ch sound advice. The illustrations are numerous d excellent, especially the coloured plates.

THORACOSCOPY.

Lehrbuch und Atlas der Laparo- und Thorakoskopie. By Dr. ROGER KORBSCH. München: J. F. Lehmanns Verlag. 1927. Pp. 74. M.12.

ENDOSCOPIC methods for the examination of the peritoneal and thoracic cavities have not made such headway in this country as they have on the Continent. Dr. Korbsch has evidently devoted a great deal of attention to their study, and he has condensed into this volume a large amount of information as to the technique used and the results which may be expected. The book is illustrated by a series of coloured plates, beautifully drawn and produced, which show the various appearances very clearly.

DICTIONARY OF NATIONAL BIOGRAPHY.

1901–1911. Three volumes, bound together. Pp. 644, 669, 739. 21*s*. 1912–1921. One volume. Pp. 623. Same price. London: Humphrey Milford, Oxford University Press.

THE Dictionary of National Biography was planned originally to end at the close of the nineteenth century, but was extended so as to contain the biographies of noteworthy persons who had died before Jan. 22nd, 1901, that being the day of Queen Victoria's death. Two Supplements were issued later by Messrs. Smith Elder and Co., whose senior partner Mr. George Smith, had devised the wonderful scheme. Each of these Supplements was in three volumes, and in format similar to the well-known series; the first Supplement contained the lives of those who had died up to the day of Queen Victoria's death and were for one reason or another not included in the original volumes; while the second contained the lives of those who had died between that date and the end of 1911, the three volumes comprising 1660 lives. This second Supplement was edited by Sir Sidney Lee, with the assistance of Mr. W. B. Owen and Mr. G. S. Woods, and was issued in accordance with the determination to continue one of the most valuable works of reference in the world by regular decennial issues. The firm of Smith Elder and Co. having been dissolved in 1916, the heir to Mr. George Smith, the founder of the Dictionary, presented the stock and copyright to the University of Oxford. Hence the Oxford University Press is now publishing the two volumes under review, the first volume (1901–11) being a reprint on thin paper of the original second Supplement, while the second volume (1912–21) is the next decennial issue. This is edited by Mr. H. W. C. Davis and Mr. J. R. H. Weaver, contains a composite index covering both decennial periods, and has for its appropriate preface a full memoir of Sir Sidney Lee. This memoir is extremely interesting not only as recording the life of a noteworthy man of letters, but as containing in brief the story of the evolution of the Dictionary. Thus we see how remarkably the great design of Mr. George Smith was carried out by the first editor, Leslie Stephen, in coöperation with the first sub-editor, Sidney Lee; we obtain insight into the way in which the ideals of George Smith, Leslie Stephen, and Sidney Lee were carried out in a composite scheme, with necessary modifications but with no abatement of the high standard determined upon. The arrangements for production and systematisation of the output, and the precautions taken to secure uniformity in quality and fitness between the subject selected and the space allotted are set out, and the following interesting piece of information is quoted from Leslie Stephen himself in justification of the inclusion of the less celebrated:—

> "The judicious critic is well aware that it is not upon the lives of the great men that the value of the book really depends. It is the second-rate people—the people whose lives have to be reconstructed from obituary notices or from posthumous works; or sometimes painfully dug out of collections of manuscripts; and who really become generally accessible through the Dictionary alone—that provide the really useful reading. Nobody need look at Addison or Byron or Milton in a dictionary. He can find fuller and better notices in any library; and the biographer must be satisfied if he has put together a useful compendium of all the relevant literature."

The volume 1901–11 includes the names among others of the following distinguished members of the medical profession: Thomas Annandale, William Mitchell Banks, Lionel Beale, Charles Beevor, G. F. Blandford, William Broadbent, H. H. Clutton, Joseph Fayrer, William Tennant Gairdner, Alfred Garrod, Samuel Gee, Luther Holden, Timothy Holmes, Hughlings Jackson, J. W. Ogle, F. W. Pavy, J. F. Payne, Vivian Poore, Sydney Ringer, Argyll Robertson, T. D. Savill, Edward Sieveking, Charles Bell Taylor, Thomas Henry Wakley, and Thomas Wakley, jun. In this list it may be that only one name will go down to posterity as a pioneer—one to whose exploratory work the solid annexations of the future are due—but every name for years to come

may find its place in medical references, thus making the student appreciative of the details supplied by the dictionary. The notices of Thomas Henry Wakley and Thomas Wakley, the son and grandson respectively of the founder of THE LANCET, both of whom succeeded to the editorial chair, are sympathetic.

The volume (1912–21) covers, of course, the four and a half years of the European war, and among the many national losses during that terrible epoch we find chronicled the names of Victor Horsley and Elsie Inglis. For the rest the list includes those famous persons Elizabeth Garrett Anderson, Sophia Jex Blake, William Osler, and the great Lister. Other names to be recalled to memory are Lauder Brunton, Henry Butlin, Thomas R. Fraser, William Gowers, Jonathan Hutchinson, Leander Starr Jameson, Wickham Legg, Edward Nettleship, William Henry Power, Felix Semon, Anthony Traill, William Turner, E. Adrian Wilson, and Charles Wyndham, a curiously interesting list because of their very varied claims to well-earned fame—claims which are so recent as to need no recalling. In this volume will be found also many names which will always be associated with the development of our profession; for example, we have biographies of two great chemists, William Ramsay and Henry Roscoe, Russel Wallace the contemporary discoverer with Darwin of fundamental truths in evolution, Adam Sedgwick the biologist, and Robert Morant, to whose personal energies and sympathy it was largely due that the profession of medicine obtained its measure of recognition under the National Insurance Acts. The volume (1912–21) is, as will be seen, very much shorter than its predecessor, and is planned on less ample lines than the older of the supplements published by Messrs. Smith Elder and Co. under the editorship of Sir Sidney Lee. It was seen that if a similar policy of selection had to be pursued throughout the present century the result would be to add about 15,000 lives (and nearly 20,000 pages of print) to the main work. The editors have therefore reduced the average length of the articles and have no doubt been more strict in the admissions to the national roll. There is one obvious justification for such a policy—namely, that in the second quarter of the twentieth century books of reference containing biographical details and small individual biographies abound. It is extremely unlikely that the historian of the future, considering the mass of contemporary material finding its way into print, could ever be at a loss for any really necessary information about anybody, where that information was of national importance.

POPULAR PHYSIOLOGY.

Living Machinery. By A. V. HILL, M.A., Sc.D., F.R.S., Foulerton Research Professor of the Royal Society. London: G. Bell and Sons, Ltd. 1927. Pp. 256. 7*s.* 6*d.*

THOSE who attended the Christmas lectures for young people at the Royal Institution last year will remember how skilfully and amusingly Prof. A. V. Hill elucidated the nature and function of nerve and muscle. It takes something very like genius to explain in non-technical language the nature of a conditioned reflex or the process of carbohydrate metabolism, and Prof. Hill has in addition to this power a charming and easy style. The six lectures here printed are on nerves and the messages they carry; muscles and how they move; the heart; the lungs and circulation, which supply the muscles with air and fuel; the way in which nerves and muscles work together, and the physiological bases of speed, strength, and endocrines. Besides many diagrams and illustrations in the text, the book also contains 24 excellent plates. Most laymen know very little about their bodies, and it is mainly for their information that such popular works as this are published. Probably many medical men may find that they know more after reading these lectures than they did before; at any rate, they will wish that all their scientific knowledge could have come to them in such a palatable form.

FRACTURES OF THE NECK OF THE FEMUR.

Le traitement des fractures du col du fém
By JACQUES LEVEUF and CH. GIRODE. Pa
Masson et Cie. 1927. Pp. 148. Fr.30.

THIS is a description of Prof. Pierre Delbet's w
on the treatment of fractures of the neck of the fe
and is an extremely interesting record of his meth
and results. The authors show that a metallic sc
is useful in younger patients and that a living autog
of bone leads to good results in a large percentag
older people. The description of the details of th
operations is a revelation of logical thought
inventiveness, not always brought to bear upon s
problems. The technique is complicated and prec
obviously demanding skill, great care, and experie
but the results indicate that its acquisition is
worth time and trouble.

METHODS OF RACIAL STUDY.

Rassen-Forschung. Von Dr. WALTER SCHEI
Privatdozent für Anthropologie an der Universi
Hamburg. Leipzig: George Thieme. 19
Pp. 80. M.5.80.

THIS little book is designed as an element
introduction to the methods to be used in racial stud
especially such studies as, starting from the gen
laws and theories of race, describe the race biol
of some given population. The introduction gi
a warning against the over-estimation of the techni
of measurement and description without adequ
knowledge of the subject matter of anthropolo
and insists on the importance of plan and hypoth
in research—of putting a definite question rat
than being content with an aimless presentation
facts, and of connecting local differences of bod
characteristics with definite national and gen
cultural manifestations.

Section I. deals with the choice and sifting of
material to be studied, and points out common err
Biased errors, such as taking a non-representat
sample, cannot be remedied simply by study
larger numbers. The tendency of any obser
again, is to lay stress on the unusual rather than
typical, such exceptions often being made fami
by their reproduction as so-called "national type
in popular pictures and postcards. No amo
of skill in computation can compensate for systema
errors in the collection of material. The choice
grouping of the characteristics to be recorded rece
careful consideration. The second section de
with elementary statistical methods, and the consta
used in the description and comparison of m
observations. The author has an unfortunate pre
ence for the mean variation over the standard de
tion, and for Lenz's approximate methods of corr
tion and regression over the more exact and commo
used product moment method. His objection
biological work to constants based on least squ
methods as putting too much weight on outly
observations does not seem to outweigh the adv
tages of the latter. These, as Prof. Karl Pearson
pointed out, are a smaller sampling error, a uni
value, and a definite meaning not limited (as
Lenz's Deutscher Korrelations-index and its deri
regression) to the case of normal distributions. Mi
defects in this section, and also in the appen
are several misprints that might mislead a beginn
a four-fold table, such as that on p. 45, in wh
one of the alternative groups to be again divi
only contains five observations, is of little value
ill-chosen as an example. References also are
complete—e.g., Mollison's formula for a type differe
is not a familiar one, but no reference as to its ori
is given.

The notes on statistical methods in the recen
published report of the British Association Commit
on biological measurements (Section D, Leeds, 19
are to be preferred. This useful little report cov
in a less detailed way most of the points discus
in Dr. Scheidt's book in their general application
biological work.

THE LANCET.

LONDON: SATURDAY, FEBRUARY 4, 1928.

THE ALLEVIATION OF DEAFNESS.

DEAFNESS is a widespread and disabling affliction, and in a large number of cases it is at present little amenable to treatment; there is, therefore, small cause for surprise that any claim for a new method of treatment as giving successful results should be widely quoted in the lay press and should arouse the interest and hopes of a large number of sufferers. This has been the fate of an article by Major V. NESFIELD,[1] recently published in our columns; so irrelevant and unjustified have been some of the comments that a brief review of the treatment of chronic deafness may be useful in the endeavour to get the subject into proper focus. Such a summary of what is known will not obtain the publicity secured by the surmises, but we feel that our readers, despite its elementary nature, may find in it counsel that will be useful to their patients.

Chronic deafness is due to various causes, which may be classified shortly in two groups: those resulting from impairment of the apparatus of perception or of the nerve-paths thence to the brain—these may be called "nerve-deafness"; and those caused by interference with the transmission of sound-vibrations through the tympanum, or "middle-ear deafness." This latter group contains three main subdivisions, the results respectively of suppuration in the tympanum, otosclerosis, and chronic middle-ear catarrh. Regarding these various forms, we cannot expect that treatment of the tympanum will do good in nerve-deafness. In otosclerosis the essential lesion is the growth of new spongy bone in the neighbourhood of the fenestræ and elsewhere in the capsule of the labyrinth; here in view of the small size and inaccessibility of the parts concerned, and of the progressive character of the lesions, surgical interference is likely to do more harm than good. In active aural suppuration timely surgical treatment is of the greatest value in curing the disease and, of course, in improving the hearing; cases of healed suppuration left with a perforation of the drum already have the tympanum open to the air, and offer no opportunity for an operation designed to give an artificial opening into the auditory cleft. The problem of healed suppuration with an intact membrane approximates to that of chronic middle-ear catarrh. This last affection is the cause of a considerable proportion of all cases of chronic deafness which are variously described under such titles as chronic adhesive catarrh, or chronic hypertrophic and hyperplastic otitis media; the essential pathology is the production of new tissue-elements in the mucosa of the tympanum and Eustachian tube, resulting in thickening, contraction, and adhesions. Inflammation has spread from the upper air passages along the tube, and the degree of deafness which it causes will depend largely on the situation of the lesions, being most severe when the fibrous changes affect the region of the fenestræ. While the thickening of the mucosa is localised principally to the Eustachian tube, restoration of its patency by catheter and bougie has a good result; but when intratympanic fibrosis has reached a high grade, treatment of the Eustachian tube has little or no effect; indeed, at a late stage, secondary atrophic changes have often restored the patency of the tube, while the internal ear is liable to become involved, as is shown by the diminution of bone-conduction. It is in this class of case, where none of the usual methods of treatment is of any avail, that various operations have been tried, mostly with the idea of admitting air to the auditory cleft, in remedy of the effect of the closure of the Eustachian tube. It must, however, be apparent, from the considerations just mentioned, that such operations can only be expected to do good when the fenestræ are not occluded by fibrosis or bony deposits, and when the internal ear is not severely involved. On the other hand, when the hearing is not improved by restoring the patency of the Eustachian tube, it is probable that intratympanic fibrosis has already occurred. It would therefore appear, on *a priori* grounds, that operative interference will be useless when the Eustachian tube is patent, and unnecessary when its patency can be directly restored, and that it can be indicated only in those rare cases where there is an impermeable stricture of the tube.

POLITZER,[2] we may recall, has stated that attempts to restore the hearing by excision of part of the membrana tympani date back to the end of the seventeenth century; they were revived, early in the nineteenth century, by HIMLEY and ASTLEY COOPER independently, but it was not long before these two operators became convinced that good results were only temporary. POLITZER maintained, and this seems obvious, that operation can only be successful if the membrane of the round window is not thickened and if there is no labyrinthine complication; he held that no improvement can be expected when perception through the cranial bones is diminished. At the Sixth International Otological Congress, held in London in 1899, Dr. ARISTIDE MALHERBE, of Paris, read a paper claiming good results from an operation in which he scooped out the mastoid down to the antrum, cut a flap in the posterior meatal wall, and kept the communication between meatus and antrum open by means of a celluloid tube. He had operated on some 60 cases, but was careful to insist that not all cases of chronic deafness were amenable to surgical treatment, and that it was indispensable to examine the patient in a systematic manner, operation being essayed only if the perception for acoumeter and deep-toned tuning-fork was not much reduced, nor the bone-conduction for the deep fork, while loss of high notes was extremely unfavourable. In spite of these very proper cautions, his procedure has fallen into the limbo of forgotten things; all surgeons are not so ultra-conservative as to refuse to try new methods, and it is fair to assume that the operation has not survived because the results did not justify its performance. It is unfortunate that a committee, appointed in Paris to inquire into his results, was discharged without having been given adequate material on which to reach a conclusion; had a number of good results been available, it is to be presumed that they would have been brought before this committee.

Major NESFIELD'S operation is planned on lines very similar to Dr. MALHERBE'S, except that he does not keep in a tube to maintain the artificial opening for more than 48 hours, and that he sinks a comparatively narrow shaft through the bone to the antrum. Those with experience in aural surgery

[1] THE LANCET, 1927, ii., 1338.

[2] Politzer's Diseases of the Ear, sixth edition, edited by M. J. Ballin. London, 1926.

know how difficult it is to obtain a sound epithelial lining to a narrow cavity in the bone, and to maintain its patency, and some remarks in our correspondence columns show that Major NESFIELD'S opening does not always remain. In his short paper he does not mention the preliminary examination on which Dr. MALHERBE insisted, and, as he has operated on patients from the ages of 4 to 70 years, it is probable that his patients include sufferers from a variety of different conditions. It is to be expected, therefore, that Major NESFIELD will supplement his paper by an analysis of his results, both as regards the hearing and the patency of the new opening, with a full description of hearing tests before and after operation in a considerable number of patients. If in this way the new evidence justifies the proceeding, it would be well that an independent committee should be formed to examine and report on a series of the cases; there should be no difficulty in obtaining the coöperation of an expert body if the circumstances reveal a need for inquiry.

PSYCHONEUROSES AND INDUSTRY.

EDUCATIONAL tests are partly tests of intelligence, but their results throw no light upon intelligence unaffected by the results of education. Hence it has been the aim of psychologists to devise tests which would measure intelligence irrespective of educational influence, and such tests have been sufficiently perfected to be reliable in educational and vocational guidance. Happiness and efficiency, however, depend upon other factors besides education and intelligence. Among these physical health comes first, and the health of aspirants to particular callings is rightly made a subject of investigation; but there is also a numerically serious group of disabilities which arise from difficulties of mental adjustment to conditions of work and apparently depend upon qualities that hitherto have not been detected either by psychological or medical examination. In his paper on the incidence of the minor psychoses, printed elsewhere in this issue, Dr. MILLAIS CULPIN shows that in some establishments there is a serious loss of time through sickness which appears under such headings as nervous debility, nervous breakdown, or cardiac and nervous strain; in other establishments these illnesses are almost or quite absent, whilst in others again they are concealed under such diagnoses as dysmenorrhœa, anæmia, or gastric disorder.

The work he describes had begun as an investigation into telegraphists' cramp, most of the sufferers from which also presented severe psychoneurotic symptoms. Non-cramp controls, however, revealed a surprising number of men and women with similar symptoms, and it was decided to examine people in other employments in order to ascertain what proportion of the general population suffered from psychoneurotic symptoms that might be reflected in sickness-rates. The proportions varied somewhat in different occupations, but the effect upon sick-rates bore no relation to these proportions. Laundry workers, for example, in whom psychoneurotic illness was practically unknown, showed little difference from clerical workers in the incidence of what Dr. CULPIN calls latent minor psychoses. Some factor besides this latent tendency must therefore determine the excessive sickness in some occupations, and here further research is required. The investigation has shown that in a single interview by a trained observer with voluntary subjects nervous symptoms can be elicited which have previously escaped the notice of their medical attendants and yet have great influence not only upon their happiness but their health and efficiency. Our conceptions of what constitutes "nervousness" in a patient have hitherto been rather vague, and if a student were invited to ascertain whether a patient suffered from nervous symptoms that might be significant for diagnostic purposes, he would be rather at a loss how to discover them. Although Dr. CULPIN does not point out its moral, yet the case of the art student who at the age of 19 had already undergone an operation for some form of visceroptosis, whilst suffering from obsessional symptoms which it is not the custom of medical men to seek for, suggests a relation between nervous symptoms and visceroptosis, whose possibility will never be elucidated until we learn to investigate the nervous symptoms. This case was cited to illustrate the curious observation that the McDougall-Schuster dotting test—used by Miss MAY SMITH in this investigation as a check upon the psychopathological findings—picks out obsessional subjects by the excellence of their performance.

That the psychological results are significant is also confirmed by Prof. MAJOR GREENWOOD'S statistical examination of the relation between them and the judgment formed by instructors concerning the capabilities of learners at telegraphy. Although the investigators had set out only with the aim of discovering whether it might be possible to detect beginners who would later become subject to cramp, yet their results were in fair accord with the opinions of the instructors, formed after several months of observation, concerning the present ability of these young people. This indicates that by their methods it may be possible to select those learners who are likely to become efficient and thus to supplement present methods of vocational selection and guidance. It is to be noted that the methods measure neither education nor intelligence, but temperamental reactions, and that in this lies their novelty as applied to vocational selection. The ramifications of this research seem widespread, but at present its most important aim is the investigation of the modern plague of "nerves" as it affects sickness-rates in industry. That it has been undertaken by the Industrial Fatigue Research Board is a recognition of its importance.

HEALTH AT SCHOOL: THE DOCTOR AND THE TEACHER.

IT is now 20 years since the medical inspection of school-children was made compulsory by Act of Parliament. The Circular of the Board of Education issued when the Administrative Provisions Act of 1907 came into force, emphasised the fact that the new legislation aimed not merely at a physical survey or record of defects but at the physical improvement—with its natural corollary, mental and moral improvement—of coming generations. Justification for this policy was to be found, not in terms of money, but in decrease of sickness and incapacity among children and in the ultimate decrease of inefficiency and poverty in after-life arising from physical disabilities. During this period of 20 years the reports of the chief medical officer of the Board of Education have served as a sort of Domesday Book of the physical condition of the English child. We need not stay to point out here how and in what degree this condition has changed owing to the activity of the School Medical Service, but it may not be amiss to remind our readers that this Service had last year a medical and dental staff of 2362 practitioners with 4779 nurses at their disposal for part or the whole of their time. Put in a word or two, the fourfold aim of

the Service has been to fit the child to receive the education provided for it, to detect any departures from health, to discover and prevent the causes and conditions of defect and disease, and to teach and practise personal hygiene in every school. In the first three aims medical inspector, specialist, and nurse can not only initiate but largely carry through their task; the fourth and chiefest aim is only realisable through the coöperation of the teachers and indeed of the children themselves. It is for this reason that peculiar interest attaches to a handbook which has just been issued.[1]

This is a Manual on Health Education, complementary to the Handbook of Suggestions for Teachers, and intended to replace the Syllabus of Hygiene for the Training of Teachers. The handbook of 83 pages is divided into two parts, one containing subject matter for health practice and health talks for young children, the other containing outlines of health lessons for older children; and more than three-quarters of the book is taken up with detailed notes upon these lessons. Those who are sometimes tempted to doubt whether there is any considerable agreed body of teaching on popular health matters will turn to these notes with a pleasurable surprise. Sir GEORGE NEWMAN, as chief medical officer, contributes an introduction on health education. Hygiene, he points out, is so essential to school life that it cannot be a mere subject of instruction; like behaviour and conduct it is the groundwork of all else. The way of hygiene cannot be found by the uninitiated child, and it is nurture rather than instruction which he requires. Hygiene should be taught to young children by habit training, although, when the elements of science and housecraft have been mastered, some degree of reasoned explanation and interpretation may become practicable. But for young children there is little need or place for instruction except in the mode of presenting health axioms and practices. One teacher may choose to make a daily inspection of the children, another may utilise the drawing lesson as an opportunity for dealing with cleanliness; the midday meal may furnish occasion for a talk about the care of the teeth, and nature-study lead to brief practical applications of physiology. For the older children health instruction may constitute part of the general science course or of a course in simple biology. Some of its substance will come into periods devoted to history and geography, while in the case of girls much will naturally form part of the teaching of domestic subjects and housecraft. The live teacher will lose no opportunity of securing the child's active coöperation in all matters of health at school and will endeavour to link up the school with the home.

Dr. R. H. CROWLEY, senior medical officer to the Board of Education, had the issue of this Handbook before him when a week or two ago he addressed the North of England Education Conference on some fresh aspects and developments of health in relation to education. He remarked how securely set had become the medical inspection of school-children in the public health service of the country and how it had contributed to the shaping of a freer curriculum for young children, to the provision of open-air schools for the delicate child, and to the planning and equipment of schools more in harmony with the child's requirements for growth and development. But in removing physical defect and preventing its onset the ground would only have been cleared for the development of the principal aim of the Service, the realisation of which was in the hands of the teacher, the doctor being called upon to guide and, perchance, to equip himself to guide. Regarding the whole process of education as in itself a biological process, function illustrated by form should be the motto of the school teacher, the subject itself being entitled to rank as fundamental with the teaching of English and the opportunity for creative work. It is easier, he said, to make health education grip in the case of girls than of boys. Domestic science—or, to use the preferable term, home economics—in the case of girls linked up the home with the school, but some equivalent in the case of the boy had yet to be worked out. It might come through further development of handyman courses, through wider acceptance of the boy-scout movement, through greater emphasis on first-aid activities, or through steps taken to interest older boys in community hygiene such as water-supply, sewage, and the distribution and care of milk. Should public education in this country develop on such lines, the charge could no longer be truly laid against the system that it is too grey.

JOHANNES FIBIGER.

IN Prof. FIBIGER, whose death is announced from Copenhagen, experimental medicine loses an exponent whose work opened a new chapter in research on cancer. His association with this disease was at first almost accidental, and before the war he was known primarily as an authority on the pathology of tuberculosis, which he had studied since his appointment to the chair of pathology at Copenhagen in 1900. It was, indeed, whilst inoculating tubercle bacilli into rats that he first observed unusual growths in the stomach of these animals. Gastric cancer in the rat had never been seen before, the coincidence of finding three cases together was remarkable, and FIBIGER set himself to discover its cause. Microscopic examination eventually revealed the presence of an unknown nematode worm in the centre of all three tumours, and by now the investigator's genius was thoroughly aroused. First he carefully examined an immense number of rats to find a similar growth, but without success. Then he discovered in the literature a report that nematode worms were sometimes found in the stomach of rats fed on cockroaches; but here again he was met by defeat, for in the laboratory he could not reproduce the phenomenon. At last he heard of a factory where there was an abundance both of rats and cockroaches, the latter being *Periplaneta americana* instead of the more usual *Stilopyga orientalis*. In this factory, it was discovered, many of the rats had gastric cancer, and the cockroaches, which came from the West Indies, had nematode larvæ in their muscles. The life-history of the worm was thus demonstrated, and by feeding other cockroaches on eggs obtained from the fæces of infected rats, FIBIGER was able to secure a supply of cancer-producing parasites for himself. Thus the lucky discovery was turned into a valuable means of advancing knowledge, for until it was made no method had been known by which cancer could be regularly induced in animals de novo. The work on irritation thus begun was carried on not only by FIBIGER himself with great skill, but also by a host of other investigators whose pursuit has had results of the utmost importance. The honours and distinctions which he received, including the Nobel Prize for Medicine in 1926, were won with the approbation of those best capable of judging his services, and we are glad to think that in England these services were given grateful recognition. His death at the age of 61 will be greatly deplored, but work on the lines he laid down is continuing all over the world.

Annotations.

"Ne quid nimis."

MENTAL DISABILITIES AND PREMATURE BIRTH.

THE question is often asked whether prematurely born infants are at any disadvantage, compared with others, once the immediate dangers of their condition have been overcome. And if this is answered in the affirmative, the problem remains whether the defects they show are due, on the one hand, to their prematurity, or, on the other, to the unknown factors by which that prematurity was caused. For many years Dr. Carl Looft has been engaged in searching for an answer to the first of these questions, in so far as it bears on the nervous system. The first step in his investigation, which is referred to in *Acta Pædiatrica Scandinavica* (1927, vii., 15), was to estimate the intelligence of 38 premature children, and he found that some three-quarters of them showed retarded mental development. This was certainly striking, but its exact significance remained uncertain because all the children examined proved to be rickety, an association of rickets with prematurity being, he says, the rule rather than the exception. As a further stage in his investigation he got histories of all premature infants born in Dr. Petersen's clinic at Bergen from 1910 to 1916. After excluding twins, and infants weighing over 2·5 kg., there were still 91 children in the series, and he managed to trace seven survivors of them in the schools in 1920. All seven showed some degree of mental retardation when tested by the Terman scale, and their intelligence-quotients ranged from 87 to 57. In the course of eight years Dr. Looft has also examined 532 backward (non-syphilitic) children attending *ordinary* schools at Bergen, and has found that there were 5·5 per cent. "in whom the cause of the intelligence defect could only have been premature birth." The interesting summary of their histories shows that here again the picture is complicated by a very high incidence of rickets. The series included two cases of Little's disease, one case of tremor of hands, and five children who had been born in asphyxia. Among 105 premature children seen in Dr. Looft's practice in ten years there were, he says, 19 cases of Little's disease (the term is here applied to cases with evidence of pyramidal, extrapyramidal, or cerebellar lesions) with some degree of mental defect or retardation. There were also ten cases of mental defect without evidence of lesions, and three of epilepsy. Syphilis is said to have been excluded in all of them, and a psychopathic family history was only obtained in one. Lastly, an analysis of the histories of imbeciles sent to the special schools showed that about 9 per cent. of them had been prematurely born.

Dr. Looft believes with some of our own prominent pædiatrists that the influence of syphilis as a cause of prematurity has been much exaggerated, and he lays stress on the importance of P. Schwartz's observation that the cerebral vascular lesions found in syphilitic stillborn infants are precisely the same as those found in others. He is a convinced adherent to the view that the principal factor in the ætiology of cerebral diplegia is hæmorrhage, whether meningeal or intracerebral, and he also supports Schwartz's mechanical explanation of the production of these hæmorrhages during labour, and attributes their frequent occurrence in premature infants to the fragility of the vessel walls, in which the elastic tissues have not fully developed. In maintaining this opinion he is on firm ground, and will probably be supported by an increasing number of authorities. In an attempt to apply the same idea to the origin of mental defect, his argument, though suggestive, is by no means so convincing. To begin with, few other observers have obtained so little evidence of psychopathic family history in mental defectives. A common association between prematurity and mental defect is certainly suggested by the facts he brings forward, but his contention that the defect was the result of prematurity is not always borne out by the accounts of individual cases. In two of his series, for instance, there are cases of microcephaly, a condition in which the morbid process seems to begin at an early stage of fœtal life; this form of amentia might be the cause, but hardly the effect of prematurity. It must be granted, however, that our acceptance of birth trauma as the cause of spastic diplegia predisposes us towards believing that mental backwardness may be due to damage to association areas. Certainly Dr. Looft's investigations are of the kind that should throw light on this important problem.

THOSE OTHER PRACTITIONERS.

DESPITE the advance of scientific medicine many kinds of quackery still stand high in popular esteem and in his address on "Those Other Practitioners" to the Abernethian Society of St. Bartholomew's Hospital on Jan. 26th Lord Dawson touched on problems that are of real importance to the profession. He began by pointing out that a quack and an unqualified practitioner are not necessarily the same thing. A quack is "a man who makes baseless and boastful pretensions for a method of treatment," and the deception may be practised primarily on himself rather than other people. According to this definition there are quacks in the ranks of the orthodox profession, whilst unregistered practitioners can be free from the reproach. Many of these ξένοι employ moreover what, applied under the right conditions, are sound and helpful methods of treatment; but they must be distinguished from the qualified doctor because they have not had years of training both in science and clinical medicine, without which diagnosis is liable to unnecessary error. Diagnosis affords the one stable criterion, and diagnosis as Lord Dawson emphatically pointed out, must always precede treatment. The latter is, of course, not a monopoly of doctors; it is the expression of an instinctive desire in all men to relieve suffering in themselves or others. To-day, said Lord Dawson, the field of treatment is bounded on one side by the ordered territories of science, but on the other side there is no boundary; it shades imperceptibly into the uncharted regions of mind, faith, and superstition, in which the unqualified practitioner finds his hunting-ground. The histories of quacks like Elisha Perkins, Mesmer, and Coué, of whom he gave an interesting account, show an almost exclusive reliance on their patients' suggestibility. The osteopath employs manipulation as well, and his gifts in this direction are often valuable when controlled by diagnosis, though they may be highly dangerous in its absence. Similarly suggestion, when directed against functional disorder, is useful. It is only when it is divorced, as in some forms of faith-healing, from other methods of treatment, and when its claims go beyond the facts to embrace developed structural disease, that it becomes pernicious. The necessity for keeping all forms of psychotherapy within the bounds of diagnosis increases, the lecturer urged, from day to day. As man's adaptive capacities are outstripped by the material resources of civilisation there is an increased incidence of psychogenic disorders, especially those known as "exhaustion states." Patients suffering from emotional exhaustion do much better when their attention is directed to a real physical treatment, while such mind-healing as they require is carried on unobtrusively. "An exploratory operation on the mind does not heal by first intention except in delicate hands," said Lord Dawson, and psycho-analysis, so useful in some cases and fraught with such danger in others, should be kept in the hands of a few highly skilled and temperamentally qualified persons; like every other form of treatment, it should be directed by the clinician, and should be based on sound and accurate diagnosis.

The main contention of an interesting address was that the true physician must possess the gift of healing both body and mind. The difference between the orthodox practitioner and "those others" is an equipment of traditional learning and ethics which not only fosters this gift but enables it to be most effectively employed for the benefit of mankind.

TUBERCLE BACILLI IN BOVINE FÆCES.

In order to study the incidence of tubercle bacilli in the fæces of dairy cattle, Dr. Stenhouse Williams and Mr. W. A. Hoy [1] examined samples taken from 38 apparently healthy cows in five English counties. Of these samples 337 were treated by the antiformin method and 101 by Petroff's method; in each case a ounce of fæces was treated and two guinea-pigs were inoculated from the sediment obtained. Neither method completely eliminated the danger of "septic" infections in the inoculated animals, and the test was not regarded as complete unless the guinea-pigs lived longer than 42 days; when possible they were kept for 600 days before being killed. Of the 391 completed tests 6 (1·53 per cent.) gave positive results, living and virulent bacilli being evidently present in the fæces. Nearly all the 391 samples were taken from cows that had not been tested with tuberculin; the exceptions were 24 cows which were known to be reactors, but (as it turned out) had no tubercle bacilli in their fæces. Examination of the records showed that five of the cows excreting tubercle bacilli came from four farms lying within a radius of three and a half miles. Since not more than one single ounce of fæcal matter from each cow was examined, and since later experiments have shown that the bacilli are excreted at irregular intervals, and that antiformin has a variable influence upon their virulence, it is probable that the tests show too small a proportion of positive results.

BACKACHE.

In commenting on a paper on sacro-iliac subluxation we recently remarked that orthopædic surgeons of repute, not only in America but also in Great Britain, seemed to have had very various experience of this condition. Somewhat similar thoughts are aroused by a suggestive communication to the *American Journal of Surgery* (1927, N.S., iii., 523), in which Dr. F. H. Albee deals with cases that may conveniently be grouped together under the homely name of backache. As a surgeon whose name is specially associated with valuable work on autogenous bone-grafting, Dr. Albee might perhaps be expected to advocate radical operation, but in fact he recommends its restriction or abandonment in favour of gentler measures. He begins by offering a pathological explanation of many apparently dissimilar conditions which are generally labelled lumbago or sciatica or (in America) sacro-iliac strain, and which he would like to see grouped together under the name "myofascitis" which he has coined to describe them. To this suggestion there are, we think, manifest objections. In the first place, its adoption would imply the existence of an affection of muscle-fibres in favour of which there is no pathological or anatomical evidence, and in the second place the term "fibrositis," which has been in use for a good many years, is applicable to the group of symptoms in question and is free from some of the objections offered to "myofascitis." It seems a pity, moreover, to burden medical nomenclature with a new Græco-Latin hybrid unless it is absolutely necessary. Dr. Albee has become convinced that a large proportion of those cases which are by some surgeons in America diagnosed as sacro-iliac strain are in reality due to "myofascitis," the chief symptom of which is pain at bony insertions elicited by tension on the involved muscle or fascia." Many of his cases had been treated for sacro-iliac relaxation and had relapsed, and he states that at least 90 per cent. of the cases of "low back pain," "lumbago," "sacro-iliac strain," and "sciatica" which have been referred to him under these diagnoses are on more comprehensive analysis instances of myofascitis, to which disorder he applies that overworked term "a clinical entity." It is really due, he considers, not so much to local injury as to faulty metabolism and absorption of toxins from the large intestine, and since reaching this opinion he has treated all such cases in which no anatomical lesion can be demonstrated by lavage of the colon, implantation of *Bacillus coli*, and restriction of proteins in the diet. In 40 cases which he tabulates the results are reported as from "good" to "excellent," except in two in which the treatment was not properly carried out and one other in which it had only just begun.

In the paper which follows Dr. Albee's in the same journal (p. 534) Dr. H. Lusskin and Dr. H. Sonnenschein, of New York, reassert the reality and frequency of sacro-iliac subluxation and arthritis, and advocate therapeutic measures similar to those recommended by Dr. D. Hoyt Cox, on which we commented some weeks ago.[1] They make no allusion to any treatment directed towards improving metabolism, and in many ways their communication is in strong contrast to that which immediately procedes it. Like many other American surgeons they find that the application of adhesive strapping is often efficacious, but in severe and resistant cases they advocate fixative operations. They say that "all patients" with this form of sacro-iliac disturbance "have aggravated weak feet." On the basis of such experience as has hitherto been recorded in this country it is difficult to decide whether the latest views of Albee, or his earlier ones, and those held by Lusskin and Sonnenschein most deserve acceptance. The sins of the human colon seem to be brought home to it with increasing emphasis as time goes on, and if Dr. Albee's last indictment results in the finding of a true bill it will furnish an additional argument for Sir William Arbuthnot Lane's attacks upon stasis.

DIPHTHERIA CARRIERS.

It has long been recognised that diphtheria carriers may discharge bacilli intermittently, and three negative examinations are usually required before a suspect may be discharged. F. H. Thomson, E. J. Mann, and J. E. McCartney [2] showed that examinations should be continued at least once a week for the first fortnight of the disease and thereafter twice weekly for three weeks. Only when six consecutive examinations had been negative could the patient be declared free. In a recent investigation into carriers, described to the Epidemiological Section of the Royal Society of Medicine on Jan. 27th, Dr. McCartney and Dr. W. C. Harvey found it necessary to study the intermittent periods very carefully. Attempts to cure a carrier may coincide with one of these periods and convey a false impression of the result. They did not consider a carrier free unless six consecutive tests spread over six weeks were all negative, and illustrated by their charts, shown on the screen, the necessity for this rigid standard. In one carrier five examinations were negative over a period of two and a half weeks, and bacilli appeared again at the sixth test. Another patient gave four consecutive negative results, then one positive followed by eight negatives. As the tonsils were large they were removed, after which the throat cultures yielded two positive results; then the nose gave one and then both remained clear. The work was carried on in the M.A.B. hospitals, and 350 carriers have been examined, swabs being taken twice weekly from the throat, each nostril, and, if necessary, from the ear. Loeffler's serum medium and a modification of Pugh's stain were used to identify the organisms, and virulence was tested by intracutaneous inoculation into the guinea-pig. The term "carrier"

[1] Journal of Hygiene, November, 1927, p. 37.

[1] THE LANCET, 1927, ii., 1302.
[2] Annual Report, M.A.B., 1925–26, p. 130.

was only applied to persons who harboured virulent diphtheria bacilli 12 weeks or more after the onset of the clinical disease. In addition, every patient was examined for abnormalities of the upper respiratory passages by Mr. Humphrey Marriner. Most of the carriers (94·8 per cent.) showed some abnormality; crusting of the nasal mucosa, enlarged tonsils or turbinates, adenoids, or deflected septum. It was found that the presence of these conditions coincided with a prolonged carrier state, and that those who had affections of ear and nose, as well as of the throat, carried longer than those with one or two lesions only. An examination of 300 unselected diphtheria convalescents served to point the moral. The proportion with healthy respiratory passages was much higher (27 per cent.), and none of them had any ear trouble. Of the 300 13 became carriers, and all of these had some clinical abnormality. Another control group was provided by 100 patients free from bacilli and ready for discharge. 48 per cent. of these had nothing wrong with their noses or throats, and the nose was affected in only 3 per cent. The majority had large but healthy looking tonsils, showing that enlarged tonsils do not in themselves hinder the natural elimination of diphtheria bacilli. The majority of carriers were between 1 and 5 years of age, so that the difficulties of examination and treatment were very great. It seems quite clear, however, from the results of these investigations, that the liability of young children to nasal catarrh with blocking of the passages is the reason why they tend to become nasal carriers. When the nares have grown larger there is less likelihood of crusting and so of the formation of pockets of inflammatory material. This corresponds very closely with the results of Dr. J. A. Glover's work on carriers of the meningococcus. Chronic carriers nearly always had some nasal defect, as he reminded the audience at this meeting, and most commonly an obstinate contact between the posterior end of the inferior turbinate and a deflected septum.

The interesting discussion which followed Dr. McCartney's paper revealed general agreement with his findings. Dr. R. J. McCann, of the Guy's Diphtheria Clinic, agreed that the nasal condition is of primary importance, and Dr. W. S. Copeman sounded a warning against indiscriminate tonsillectomy as a cure for carriers. He had investigated a number of tonsils removed for this reason at Great Ormond-street Hospital and had never found diphtheria bacilli beneath the surface. Only the pure tonsil-carrier, as Dr. McCartney agreed, benefits from the operation. Dr. Graham Forbes, recalling the increasing incidence of carriers and the probability that such an increase precedes an epidemic, remarked on the inadequacy of the efforts at present made by the London County Council to deal with the carrier. Here was another aspect of that much discussed little person "the pre-school child." Whether or no Dr. Forbes's sense of inadequacy is justified seems to be a pretty problem. A group of fever hospital superintendents, headed by Dr. E. W. Goodall, dared to defend the status quo. "Do these tests substantially lower the return case rate?" they pertinently asked (the rate is under 2 per cent. as things are). Dr. Goodall said that he had always felt anxious about discharging patients with abnormalities of the nose, but had not observed any serious results. Dr. J. D. Rolleston said that there had been no increase in the number of return cases in his district during the last two years, although he had given up routine cultivation of swabs. Dr. E. H. R. Harries [3] has shown that the carrier-rate can be reduced to negligible proportions without prolonged routine testing. Dr. McCartney, in reply, admitted frankly that he was not concerned with the practical aspect; he and his colleague had wanted to collect some facts about diphtheria carriers and had done so. Whatever superintendents may decide to do in the matter, there remains a very practical lesson in preventive medicine. Rhinitis was a constant feature in all the cases examined; in fact, Dr. Harvey does not think that carriers harbour bacilli in living tissues at all, and the general improvement coinciding with the cleansing of the filthy nose was most striking. It is reasonable to suppose that many cases of diphtheria, meningitis, and, probably, other conditions could be prevented altogether if mothers and nurses could be taught to keep the nasal passages of small children clear by thorough cleansing of the nostrils and the daily introduction perhaps of a drop or two of some simple antiseptic oil.

ASTHMA AND AFFECTIONS OF THE SKIN.

A RELATIONSHIP between diseases of the skin and asthma has long been known to exist, and a recent study [1] by Dr. K. H. Baagöe, of Copenhagen, has added to our knowledge of this relationship. His material consisted of 124 asthmatics, 92 of whom were children, the remaining 32 being adults. Among the 124 patients there were 74 with a history of some skin disease such as prurigo, urticaria, pruritis or local œdema. Among 35 suffering from infantile or Besnier's prurigo, there were as many as 32 who gave a positive reaction to cutaneous tests, 29 to feathers, 10 to hair, 14 to foodstuffs, and 5 to pollen. Only in three cases was there a doubtful or negative reaction. Cutaneous tests carried out in 32 of the 34 cases of urticaria gave a positive reaction in 25 cases, in 22 to feathers, in 9 to hair, in 8 to foodstuffs, and in 7 to pollen. Cutaneous tests were also carried out in all of the 14 cases of pruritus, the reaction being positive in 9 of these cases. With regard to the six cases of local œdema, which most frequently affected the face, lips, and mouth, it was possible to demonstrate a relationship in four of them between the œdema and the patient's idiosyncrasy to certain substances such as eggs or fish. All six patients gave a positive skin reaction, 5 to feathers, 3 to hair, 3 to foodstuffs, and 3 to pollen. Altogether 57 out of 70 patients with diseases of the skin submitted to cutaneous tests gave a positive reaction. Only in 13 cases (11 children and two adults) were the reaction doubtful or negative. Among 50 other asthmatics (35 children, 15 adults) with no skin affections, there were 30 giving a positive cutaneous reaction. Unfortunately no control observations were carried out to show whether the skin diseases already referred to were as common in persons without asthma as in asthmatics. But, as Dr. Baagöe points out, there seems hardly to be any reason to doubt the existence of a common ætiological factor in those cases in which the skin disease broke out in conjunction with the asthmatic attack. The establishment of an ætiological relationship is, of course, more difficult when cutaneous eruption occurs independently of an attack of asthma, perhaps even at a time when the patient has not yet had any attack of asthma. Dr. Baagöe points out that the skin diseases he has observed in connexion with asthma have the following features in common: they occur in paroxysms, are characterised by hyperæmia, œdema, and itching, and are frequently if not always, due to some idiosyncrasy. With this common denominator it is natural that these diseases should be classed in one group as allergic or idiosyncratic diseases of the skin.

THE EMPLOYMENT OF TUBERCULOUS PATIENTS.

THE question of how to deal with tuberculous patients after their discharge from sanatoriums, especially those following unsuitable occupation or living or working in unsatisfactory conditions, is one of the most difficult of all the problems connected with tuberculosis and one for which no general solution has yet been found. A large number of schemes have been tentatively brought forward from time to time, chiefly in this country and in America, but most of these are impracticable from an economic point of view, while others can at best deal only with a small fraction of the patients. The subject was brought up at the recent meeting of the Tuberculosis Society (a

account of which will be found on p. 233), but no new solution was arrived at, and the only scheme brought forward was one for teaching the patient while in the sanatorium a trade which he could afterwards carry on in his own home, the necessary tools and raw materials being provided. The cost of such a scheme would, however, obviously be prohibitive on a large scale, and on the whole the training of adults in a new occupation, regarded as suitable on medical grounds, has not proved of much value.

In a report by Dr. F. N. Kay Menzies [1] the whole subject is discussed afresh, and although Dr. Menzies has no new policy to bring forward the conclusions arrived at and the data on which they are founded are of considerable interest. He points out that during the war, "when work and good wages were obtainable by anyone capable of doing any work, the unemployed tuberculous problem disappeared," and he believes that a wave of prosperity, resulting in a demand for labour, would again lead to the widespread absorption of tuberculous labour, even though the working capacity of tuberculous persons whose disease is not arrested is not more than 50 per cent. of that of a normal person. Under special conditions—e.g., types of employment which call for little physical effort, short hours, and hygienic environment—tuberculous persons are capable of working, but Dr. Menzies makes it abundantly clear that "under any circumstances, a commercial undertaking employing tuberculous employees and paying a wage adequate for their maintenance cannot be run without considerable financial loss and must be subsidised in some way." A critical examination of possibilities of employment by private employers or in specially selected jobs under public authorities, or in workshops and undertakings specially organised for the purpose, suggests that an industrial settlement run in connexion with a sanatorium is more easily organised than an independent workshop, but Dr. Menzies finds that such settlements are not only costly to establish, but they are also definitely limited in regard to the number and character of the cases for which they are suitable. Moreover, their extension on a large scale may, he thinks, prejudice the few which have already attained a measure of success. It is disappointing to learn that "it has not so far been found possible to provide the benefits of regular work at a cost which allows of an employment scheme being considered as a practical policy for general adoption," the most that can be said being that, with careful management, a certain number of selected cases could possibly be employed at a cost less than that entailed by their complete maintenance out of the rates. Wherever possible Dr. Menzies urges that a tuberculous person should seek for an employment for which his previous experience fits him, the best course, as a rule, being his return, perhaps under modified conditions, to his usual employment.

Vocational training does not seem to have been a success, judging from the general opinion of tuberculosis officers and others. Such training in skilled or semi-skilled occupations may possibly be justified in exceptional cases or in special circumstances, but Dr. Menzies considers it unlikely to be of practical value as a part of the organised scheme for dealing with tuberculosis throughout the country. The teaching of simple handicrafts, however, in sanatoriums and tuberculosis dispensaries is valuable as a means of usefully employing the time of the patients and of diverting their minds, even where such occupation is of no economic value. The question of the employment of tuberculous women is carefully gone into. Dr. Menzies believes that a workshop for such women on the lines of the Altro workshops in America would be worth consideration, another satisfactory course being the employment, where possible, of women ex-patients in domestic and other duties in connexion with sanatoriums and similar institutions. Dr. Menzies recalls that in 1926 the Metropolitan Asylums Board were obliged to postpone opening an institution for advanced cases of pulmonary tuberculosis on account of the difficulty of obtaining nursing staff, partly owing to fear of infection. It will be remembered that the Ministry of Health, in a circular issued in December, 1923, laid down a scheme for coöperation between the managers of the various employment exchanges of the Ministry of Labour and the tuberculosis officers, with regard to the employment in suitable occupations of male patients on discharge from sanatoriums or hospitals. The scheme does not appear so far to have shown many good results, possibly owing to the large amount of unemployment in the country at the present time. Very few of the metropolitan borough councils would appear to have utilised the scheme to any extent, judging from a summary, given in an appendix to Dr. Menzies's report, of replies from several of these councils to a circular letter sent out in July, 1927, inquiring as to the working of the scheme. Reference may be made here to a paper by Dr. John F. Russell, which was published last year,[2] in which the writer argues that working people cannot as a class be treated successfully at sanatoriums owing to the prohibitive cost, both to patient and to institution, of a sufficiently prolonged period of treatment. He urges that municipal dispensaries might be utilised in the place of sanatoriums, thus allowing the patient to live at home, to carry on his regular full-time work—where his physical condition allowed it—when, because the cost to the community would be small, he could continue treatment indefinitely. The writer points out that the mental and physical strain is much greater in working at a new and unfamiliar occupation than it is in continuing a usual one; in the latter case the exercise necessary to continue work is habitual and the body has acquired tolerance. While Dr. Russell is not prepared to say that this method would be best for all classes of patients with pulmonary tuberculosis, he is convinced that it is the only method available for the proper and continuous care of tuberculous patients of the labouring classes.

The whole question is big with difficulties, but one thing, at any rate, is certain: that, in Dr. Menzies's own words, every factor which tends to bring tuberculous persons under treatment when the disease is still curable diminishes the flow of patients into the ranks of the unfit and unemployable. The advantages of early diagnosis, followed by treatment sufficiently prolonged to bring about full restoration of health and working capacity cannot, therefore, be over-stated.

A SHOCKING FILM.

SOME of the difficulties inherent in propaganda against venereal disease are illustrated in a film called the Dangers of Ignorance now being exhibited for Wardour Films, Ltd., at the Court Cinema, Tottenham Court-road, London. The producers have aimed at preaching "a powerful human sermon dealing with the social evil which is undermining the physical and mental health of the nation," and their attempt has won the approval of the Central Council for Health and Education set up a few months ago by the Society of Medical Officers of Health. It thus bears an official medical cachet, and we are informed that a proportion of the takings is to go to the Council's funds; but exhibition of the film is due to private enterprise and the public is encouraged to see performances by descriptive "catchlines" such as "a medical picture visualising the terrible havoc resulting from pandering the sexual passions . . ." "depicting cold scientific demonstrations on the horrors following in the train of venereal disease." When this has been said it must be admitted that the general tone of the production is good and that the instruction is both clear and convincing.

The film is divided into four parts, in the first of which we are introduced to a couple of ignorant youths at a "fair" resembling the amusement park at Wembley. Seeing them solicited, a watchful

stranger directs their attention to a pavilion labelled "sexual diseases" where an elderly lecturer is giving an account of the damage done by gonococcal infection. The captions accompanying his address are often too technical for a lay audience, making free use of words like "mucous membrane," but the point of his teaching can hardly be missed by anyone who keeps an eye on the models that show the manner in which the organisms reach their various locations in the human body. The genital tract is seen in sagittal section and gonococci, neatly paired and the size of small beetles, make their way with terrifying precision into the anterior and posterior urethra, the prostate, epididymis, bladder, uterus, or Fallopian tubes, according to the stage reached by the lecturer in his argument. Further models show the mechanism of infection of the mucous membrane, the reaction of the tissues, and the formation and spread of pus. The technique of their construction is so good that the photographs would not come amiss in a lecture to medical students. Particularly effective are those which show cicatrisation in the epididymis and Fallopian tubes, leading to sterility, and the lesson that treatment must not be abandoned before cure is brought out with all possible emphasis. Reiteration of the same lesson continues throughout the rest of the film, which tells the stories of a number of people who have contracted venereal disease. The first, a young student, is attacked by gonorrhœa after visiting a prostitute. Fortunately he meets a venereal specialist and his case is early taken in hand, so that after a fortnight no more cocci can be found in his urethral discharge. He is then inclined to laugh at the idea of further treatment, but the laugh is turned to a prayer after the doctor has taken him round his private wards to see the plight of those whose disease is chronic, and the damage which they can inflict upon women and children. Models are again invoked to show how gonococci get into the blood stream, and patients with arthritis and endocarditis are shown to point the moral. Finally the student asks what he can do, when cured, to prevent this loathsome infection ever occurring again, and is told that there is only one sure safeguard—complete abstinence from promiscuous intercourse. That such abstinence is desirable from the point of view of innocent third parties is the message of the next section of the film, in which a baby is found to have developed a syphilitic chancre by contact with his nurse. She in her turn has been infected by a man in the park who told her that "there's no harm in a kiss," and gave her one. The disease has been allowed to reach the secondary stage because she put herself under the care of an imposing quack, and the net result of her ignorance is to infect a child and throw her out of occupation. The doctor gives her domestic work in his hospital, where she has ample chance of seeing, ad nauseam, the late effects of her disease. Their horror is further rubbed into the audience by the fourth part of the film, whose scene is laid in the familiar mortgaged homestead of cinema-land, but departs from type in that the farmer is a physical wreck, has no children, and has had to watch his wife develop G.P.I. as a result of his early indiscretion. Her destructive mania wrecks the home, and they are taken to the poorhouse. Their sole support, a niece, goes to the city, gets work in a draper's, and is seduced by a young man who gives her syphilis. The rest of the film is devoted to her efforts, under medical influence, to induce him to go on with treatment for the necessary period of years. In this she is at last successful, the doctor approves their union, and the story ends a year later when the grateful parents bring a healthy child to receive his blessing.

Enough has been said to show that powerful arguments are presented in favour of early and complete treatment. Fear is the instrument used to gain this object, and there is no doubt that it is often effective. On the other hand, it is easy to produce more of this emotion than is strictly necessary and to associate it too widely. It is a mistake, for instance, to imply that kissing is a common means of conveying syphilis; the section in which a nursemaid lapses in this way and thus becomes responsible for infecting a baby is likely to cause an immense amount of anxiety among girls and boys who have kissed a stranger and will do so again. The minds of young people are already too often disturbed by fears relating to sex, and there are too many morbid obsessions about microbes. In general the public needs to be taught about health rather than disease, and it would be unthinkable if films were exhibited to show the ravages of all the diseases which different medical authorities regard as preventable. In the case of syphilis and gonorrhœa, however, there is exceptionally good reason for instruction about the results of untreated infection and about the way in which this infection is conveyed. The instruction must be emphatic, but it loses nothing by leaving a good deal unsaid. Information on these subjects is better conveyed individually than to large audiences, but the good done by showing such a film as the Dangers of Ignorance probably more than compensates for the bad. It would, however, gain by considerable curtailment of the pathological items. We note that, unlike the ordinary erotic drama, it is shown to men and women at separate performances, a needless sop to sentiment, as the general effect it produces on the mind is nothing if not sobering.

THE EMPEROR FREDERICK'S FATAL ILLNESS.

IN a paper recently published in the leading Dutch medical journal [1] Dr. H. T. Deelman, professor of morbid anatomy at Groningen, describes the result of his examination of a laryngeal tumour sent to him by Prof. Burger. On naked-eye examination the growth appeared to be a papilloma, and this view was confirmed by the microscope, which showed, however, that in close proximity to the papilloma was a second small growth which proved to be a carcinoma. This case, as Prof. Deelman points out, is not only of practical importance, but also bears on a historical incident which had far-reaching consequences. It is clear that if the small tumour had not been included in Prof. Burger's incision the patient would undoubtedly have returned later with a typical carcinoma at the site of operation. The conclusion would then have been that the clinician and pathologist had both made an erroneous diagnosis and that the tumour excised had really been malignant after all. The historical interest of the case lies in its application to the last illness of the German Emperor, Frederick the Third. It will be remembered that 17 months before his death at the age of 56, the Crown Prince, as he then was, developed symptoms of a laryngeal affection. A papillomatous growth was found on the left vocal cord and was destroyed by the cautery without a pathological examination having been made. Owing to repeated recurrences in which the cautery was employed on each occasion, a diagnosis of carcinoma was arrived at, and Sir Morell Mackenzie was summoned from London to give an opinion. Mackenzie declared that the tumour was a papilloma and sent a portion of it for examination to Prof. Virchow, who confirmed the diagnosis of a benign tumour. The Crown Prince, who desired to attend Queen Victoria's Jubilee, came over to England, where conservative treatment was carried out by Mackenzie. Three months before his death Frederick became Emperor and a rapid aggravation of the laryngeal disease set in. Mackenzie finally decided in favour of the diagnosis of cancer of the larynx, but by this time it was too late for a radical operation. Prof. Deelman considers the three possible theories as to the nature of the growth. He dismisses the view that the tumour was primarily a papilloma which was subsequently transformed into carcinoma, on the grounds that such an occurrence is extraordinarily rare. The second explanation, that the growth was a carcinoma from the first, and that with the possible exception of Gerhardt all Frederick's medical attendants were mistaken, also appears unlikely. A far more probable explanation is that there were two growths, a benign and a malignant, not

[1] Nederlansch Tijdschrift voor Geneeskunde, Dec. 24th, 1927.

necessarily of simultaneous development, and that finally the cancer rapidly increased in size and in its destructive effect.

A TESTIMONIAL TO SIR DAWSON WILLIAMS.

THERE is a widespread feeling that the retirement of Sir Dawson Williams from the post of editor of the *British Medical Journal* after 30 years of distinguished service should not pass without some recognition from the profession as a whole of his great services to medical journalism and so to the science and practice of medicine. A small executive committee has been formed with the view of sending invitations to representative members of the medical profession and others having close associations with it; this precedes the issuing of a general appeal and the decision upon the form of the testimonial. Though the committee does not wish to limit the amount of individual donations, it hopes that the sum eventually subscribed will include a large number of contributions, and so represent the profession throughout the country. Sir StClair Thomson is acting as treasurer of the Fund, and cheques should be made payable to him and sent to 64, Wimpole-street, W. 1, the envelope maked "Dawson Williams Testimonial." A fuller statement will be made later in the medical press.

THE BUNDABERG DISASTER.

DURING the week reports have appeared in the daily press of the death at Bundaberg, Queensland, of 12 children "as the result of antidiphtheria inoculation." There is not sufficient information available at the moment to explain clearly what has happened. One of the doctors consulted in Australia suggests "that the serum may have become contaminated"; the absence in the cables of mention of any of the obvious diseases such as tetanus, anthrax, gas gangrene, or septicæmia likely to be caused in this way is against the hypothesis of contamination. Another suggestion is to the effect that latent properties "became active" in the prophylactic and a virulent poison developed. This phrasing leads one to suppose that a toxin-antitoxin mixture was in use. Such mixtures have been described in articles in the Australian medical press and in the only list at our disposal of materials prepared by the Commonwealth Serum Laboratories, from which the product is said to have come, toxin-antitoxin mixture appears as the prophylactic issued. The violent toxicity of the prophylactic could conceivably arise from dissociation of the mixture with destruction of the antitoxin, or alternatively from error in the filling and packing of untested or toxic material. Dissociation of toxin-antitoxin was clearly the cause of the accident in Massachusetts in 1924, when mixtures were exposed to extreme cold during unusually severe weather[1] In connexion with the Baden (Austria) misfortune in 1924, when a number of children died, two explanations were given—the issue of toxin in mistake for toxin-antitoxin, or dissociation of toxin-antitoxin mixture with resultant toxicity; Grassberger's report was in favour of the former. In a more recent Russian disaster [2] 14 children received toxin in place of anatoxin (i.e., toxoid); eight of them died within two weeks, four of polyneuritis within a month and two recovered after symptoms of general intoxication. Here there seems to have been simply human error. The cumulative effect of these accidents will no doubt be to make people inquire to what extent they are exposed in England to similar risks. The answer is one to inspire confidence in the present procedure, for it appears that almost all the immunisation in this country is carried out with toxoid-antitoxin mixture. On inquiry from the Wellcome Physiological Research Laboratories we are informed that in the preparation of this prophylactic the toxin is detoxicated with formalin until at least one human dose is not lethal to a guinea-pig. During many years' experimental work with various chemical and physical agencies and long storage it has not been possible to change toxoid to toxin. The toxoid is next mixed, as an extra safeguard, with a calculated quantity of antitoxin. Of this mixture 5 c.cm. will not kill any of five guinea-pigs injected, but will produce in the animal high immunity. As a confirmatory test, the toxoid-antitoxin mixture in the form in which it reaches the patient must be so devoid of toxicity that 1 c.cm. taken from each size of phial filled from each bulk bottle will fail to produce any symptoms in guinea-pigs kept under observation for ten days. These tests are more exacting than the minimum prescribed by the Therapeutic Substances Act, the main provisions of which are already in force. It would appear that there need be no hesitation in offering prophylactic immunisation to all who desire it here.

"FRIGHT DISEASE" IN DOGS.

MUCH attention is now being paid to a curious canine disease which in the last 12 months has increased in this country to an alarming extent. It is seen especially among sporting dogs and packs of hounds, and the owners of affected dogs, in describing the symptoms, have repeatedly remarked that the animal seems suddenly to have seen a ghost. Although to all appearances in perfect health, it gives a curious howl of fright and rushes away, often without any apparent idea of direction, in a state that seems to be terror. This condition may last only for a few moments, recovery being almost as rapid as onset, but on the other hand, it may be half an hour or more before the animal recovers its normal appearance. The cause has not yet been determined, and Prof. F. T. G. Hobday has issued an appeal to the public for funds, wherewith scientific research on the disease can be conducted at the Royal Veterinary College, of which he is the principal. At the present time the treatment which has been found most successful is removal of all biscuit from the dietary, combined with keeping the patient as quiet as possible for at least ten days or a fortnight, and the administration of nerve sedatives. The proportion of actual fatalities from the disease itself is negligible, but the appearances are very alarming, and dogs have sometimes injured themselves severely by violent collisions in the course of their frantic movements. The condition is said to have been observed first in America some five or six years ago, and it is rapidly increasing in that country. Such interesting symptoms should well repay careful study, and we hope that the necessary funds will at once be made available in response to Prof. Hobday's appeal. So far as can be judged, the disease seems to be peculiar to dogs, for veterinary practitioners assert that nothing identical with this "canine hysteria" has been observed in any other species of domesticated animal.

Mr. H. L. Eason, C.B., C.M.G., M.S., superintendent of, and senior ophthalmic surgeon to, Guy's Hospital, has been appointed to represent the University of London upon the General Medical Council.

A RECEPTION will be held in the House of the Royal Society of Medicine, 1, Wimpole-street, W., on Wednesday, Feb. 15th, at 8.30 P.M., when the guests will be received by the President, Sir James Berry, and Lady Berry. At 9.15 Colonel W. P. Macarthur, professor of tropical medicine in the R.A.M. College, will give an address entitled Some Medical References in Pepys.

OWING to ill-health Sir Arthur Chance has resigned his positions as representative of the Royal College of Surgeons in Ireland on the General Council of Medical Education and Registration and on the Irish Free State Medical Council. His place on the General Medical Council will be filled by Sir William Taylor, and on the Irish Council by Mr. R. C. B. Maunsell. Sir Arthur Chance had been a member of the General Council from 1911 to 1914, and continuously since 1915; he was a member of the Irish Council since its establishment last autumn.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CCLXI.

THE TREATMENT OF IMPOTENCE.

IMPOTENCE is the inability to perform satisfactorily the sexual act and is a condition quite independent of sterility. An impotent man is not necessarily sterile; nor is a sterile one impotent, although failure to consummate normal coitus is naturally a handicap to fertility. Cases of impotence may be divided into two classes, *secondary* impotence in which the disability is the result of an organic lesion in the genitalia or elsewhere in the body, and *primary* impotence in which no such lesion can be found.

Secondary Impotence.

The lesions of the genitalia that may give rise to impotence are numerous, but are not often met with in practice. Amongst them may be mentioned ectopia vesicæ, hypospadias, induratio penis plastica, elephantiasis, and arrested development of the penis, the result of some such glandular deficiency as eunuchoidism. More common are those cases in which the impotence is the result of lesions situated elsewhere in the body. In this connexion diseases of the central nervous system are of the greatest importance, and for this reason every case of impotence should be submitted to a careful neurological examination in order that such diseases as early tabes and disseminated sclerosis may be excluded. It must also be remembered that the disability may be secondary to any impairment of the general health, or to such conditions as diabetes, thyroid insufficiency, and the taking of drugs. In old age it may be physiological, although men differ widely in the age at which the sexual power is lost.

Sometimes, when an organic lesion is found, it does not appear sufficiently grave to explain the impotence. As an example may be cited the impotence that may follow an infection of the genital tract or a comparatively trifling operation on the bladder or genitalia. In these cases a psychological factor can generally be discovered, the patient having developed a fear that his previous trouble may have impaired the sexual function. Such cases really belong to the type of impotence now to be discussed.

Primary Impotence.

In these cases no lesion can be found either in the genitalia or elsewhere in the body to account for the disability. The patient is usually of the psychopathic type, intelligent, introspective, emotional, and nervous. He must be carefully handled, as it is only with great difficulty that he gives his confidence, and unless that confidence is gained nothing can be done to help him. In the majority of cases his disability is only discovered after marriage, for such men are more likely than not to have been continent previously.

Careful inquiries should be made on the subject of any previous sex experience, nocturnal emissions, and the efforts that have been made to consummate marriage with their results. Sometimes the impotence will be found to have been preceded by a period of incomplete erections with premature ejaculation and frequent nocturnal pollutions. During the interrogation the patient should be encouraged to speak freely, so that an insight may be gained of his knowledge of sexual matters, and a clue obtained to his particular psychological problem.

In some cases the impotence will be found to be a symptom of a well-established neurosis, and the only method of dealing with the patient will be to place him in the hands of a competent psychotherapist. In other cases the detection of the psychological cause of the trouble presents less difficulty, and the practitioner will feel capable of dealing with it himself. Here it is possible only to give a few examples of some of the simpler problems that may be met with.

Fear is by far the commonest factor in the production of functional impotence, and sometimes the particular form of fear which is at the root of the trouble may be discovered in the course of the preliminary conversation. The majority of men have at one time or another masturbated, and not infrequently there has become linked up with the practice the fear that permanent damage has been caused entailing loss of sexual power. With such patients it is only necessary to dispel this illusion in order to cure them. Another type that is commonly met with is the patient who has been brought up since childhood to regard anything connected with sex as something that is essentially unpleasant and wrong. Any sex urge that he may have felt prior to marriage has been sternly repressed, and even when he is married, although the taboo placed on sex may have been superficially removed, the old sense of guilt still persists in his subconscious mind and inhibits coitus. In order to cure such a patient a complete change in attitude towards the whole subject of sex must be effected. This may only be achieved with great difficulty, and the help of a skilled psychologist will almost certainly be required.

It is, of course, necessary to make sure that actual impotence exists before embarking on any treatment, as a patient may easily be wrong in his conclusions. I have seen more than one patient who has mistaken the outpouring of secretion from the secondary sex glands that takes place at times of sexual excitement for an emission of semen, and has persuaded himself that this denotes premature loss and impotence.

The Partner.—It may also be discovered in certain cases that the failure to consummate marriage is due to a mechanical obstruction in the passages of the female partner, and that normal coitus can take place when this has been dealt with. Less favourable are those cases in which the difficulty offered by the partner in marriage is not a mechanical but a psychological one. Impotence may be relative—that is to say, while remaining impotent with one partner the patient would be quite capable of consummating the sexual act with another. In some cases in which impotence supervenes some years after marriage, the explanation will be found in a transference of the patient's affection to some other woman. The patient himself may not be conscious that such a transference has taken place, and yet to the doctor the true state of affairs may be obvious.

As Freud has pointed out, for the complete realisation of the sexual life two "trends" must become fixed harmoniously together—namely, the sentiments of tenderness and of sensuality. Only too frequently the fusion of these two sentiments is incomplete, so that a man may find that in his marriage he is able to satisfy his sentiment of tenderness but not his sentiment of sensuality. The handling of such cases is fraught with difficulties and at the best only a compromise can be effected.

Allied to these is a large group of cases in which the sexual act can only be carried out provided certain conditions have been satisfied. The patient himself may not be conscious of the setting demanded for the successful carrying out of the act. The investigation of any dreams that are associated with nocturnal emissions or fantasies that have been held in the mind during masturbation may indicate the direction that further psychological research should take.

Adjuvant Measures.

It will be seen, therefore, that the treatment of primary impotence is almost entirely psychological, and that not infrequently it demands knowledge that only a skilled psychologist is likely to possess. Other measures, although of secondary importance, are often useful. Whilst under treatment such

patients should be forbidden to attempt intercourse, and, if possible, should sleep in a room by themselves. As a rule, it is advisable that the medical man in charge of the case should see the wife personally in order to explain to her the reason for this change, enlist her help, and, most important of all, prevent the arising of difficulties that are only too likely to have an unfavourable repercussion on the patient himself. In some cases it will be found that the mere forbidding of intercourse acts as a stimulus. Attention must also be paid to anything that affects the patient's general health, and he should above all be cautioned against overwork. It is a common delusion amongst such persons that they can return from their offices at the end of an exhausting day and yet retain sufficient energy to carry out an act which involves the expenditure of a great deal of emotional and nervous force. In those cases in which erections occur but are associated with premature ejaculation, benefit may result from the instillation of silver nitrate (grs. x. to the ounce) into the posterior urethra through an Ultzman catheter and syringe. Electricity is useful chiefly on account of its suggestive action, and for this reason is more likely to be effective than aphrodisiacs. Tonics, cold baths, douches, exercises, diathermy to the prostate, injections of testicular extracts or other glandular products may all have stimulative value. In nervous patients and those who have completely lost confidence as the result of past failure a small quantity of alcohol taken before resuming sexual relations may produce the proper "devil-may-care" attitude that is essential to success.

Conclusion.

The majority of patients who retain memories of many failures are likely to attempt coitus when the period of abstinence is at an end in a frame of mind that is almost certain to produce failure. The sexual act, instead of being a natural and almost mechanical reaction associated with a certain amount of pleasurable sensation and emotion has become for them a test at which they are almost certain to fail. The least subsidence of erection is noted and is taken as an omen of failure, and instead of pleasurable emotion there exists a state of anxiety and fear. For this reason the first coitus attempted after treatment is a critical period, and much judgment will be required on the part of the physician in charge to prevent disaster. The patient should be told that on no account must any deliberate planning take place as to when coitus shall be attempted. The act should be entirely spontaneous, and if better erections be present in the morning on awaking than at night—as is not unlikely—coitus should take place at that time. Moreover, an endeavour should be made to induce both husband and wife to regard the question of whether coitus is or is not achieved as of secondary importance, so that the element of anxiety may be reduced as much as possible. The fear of failure and the existence of a difficult situation between the two partners are both factors that militate against success, and must, therefore, be eliminated as far as is possible. Once the act has been achieved and confidence regained, the battle will have been won, and any artificial aids that may have been used during the period of preparation can be laid on one side.

KENNETH M. WALKER, F.R.C.S. Eng.,
Surgeon in Charge of Genito-Urinary Department, Royal Northern Hospital; Surgeon to St. Paul's Hospital.

VOLUNTARY HOSPITALS AND PUBLIC AUTHORITIES. The Council of the Charity Organisation Society propose to discuss the question of the Voluntary Hospitals and the Public Authorities at a special meeting to be held at Denison House, 296, Vauxhall Bridge-road, London, S.W., on Monday, Feb. 13th, at 3.30 P.M. The chair will be taken by Lord Dawson of Penn, and the speakers will be Sir William Hamer, Dr. Graham Little, M.P., and Dr. Humphrey Nockolds. It is hoped that representatives of the voluntary hospitals and public authorities of London and Greater London will take part in the discussion.

Special Articles.

OUR HOSPITAL SYSTEM:

REALITIES OF THE PRESENT AND HOPES FOR THE FUTURE.*

BY ERNEST W. HEY GROVES, F.R.C.S. ENG.,
PROFESSOR OF SURGERY, BRISTOL UNIVERSITY.

I HAVE been greatly encouraged in upholding this thesis since I put it forward last June, by the very many medical men who have given it their support and by the very few who have come forward to defend the voluntary system. I fear the latter source of encouragement is illusory, as it is probable that a large number of people are so satisfied about the merit and stability of the system that they think it unnecessary and superfluous to defend it. Lastly, I have been encouraged by the defence put up recently by Dr. Graham Little, M.P.,[1] because so many of his admissions are fatal to his argument and because he has been driven to so many irrelevancies and inaccuracies in order to make good even such a poor case as he had. I shall refer to these points as they occur in the course of the present argument.

Definition and Description of the Voluntary System.

At the outset we are faced with the difficulty of giving a fair definition or description of the system we have to discuss. But this is imperative for any useful argument, because many hospitals having adopted other than voluntary principles, nevertheless retain the name, but confuse the issue.

What, then, are the essentials of the voluntary system? I would suggest that they may be summarised under five headings—viz. (1) free gift of land and buildings; (2) free-will maintenance by private endowment or voluntary subscription; (3) private management by donors or subscribers, or by their trustees and representatives; (4) free medical service; (5) a charity bestowed by the rich upon the poor. A sixth condition frequently occurs—viz., limitations imposed by the terms of the gift such as that the hospital is to serve a special locality, or to admit special cases, or to serve a special cult such as homœopathy or antivivisection.

Up to the beginning of the present century most of these essentials were carried out by the voluntary hospitals, but in recent years, and especially since the war, they have been so very largely modified or superseded that it may be very well argued that already the purely voluntary system has disappeared. So much is this the case that if we are challenged to say whether the voluntary system can survive we might begin by saying that in the original meaning of the term the voluntary system is already dead.

Present-day Violations of Voluntary Principles.

In the first place, maintenance by free-will gifts and endowments has had to be supplemented by various expedients. Parliament has had to make a grant of £500,000; patients themselves are required to contribute towards their own maintenance, and the sum thus contributed amounts to about 18 per cent. of the total upkeep; insurance schemes have been adopted whereby groups of workpeople are paid for during their stay in hospital; patients are paid for by poor-law or municipal authorities; and even the so-called voluntary subscriptions are now largely made up by a system of appeals, advertisements, lotteries, mendicancy, and blackmail unworthy of a great nation or of a great national service. Again, free medical service has had to be more and more supplemented by that of a paid staff. Not

* Being the opening address in a debate held by the Bath and Bristol Branch of the British Medical Association on Jan. 25th, 1928, on the subject—The Needs of the Community Require a Better Hospital Service than that Provided by the Voluntary System.

[1] THE LANCET, 1927, ii., 1275.

only have whole-time paid residents been increased and emoluments raised, but also a certain number of non-resident specialists, such as pathologists or anæsthetists, and in some places whole-time professors of medicine, surgery, or midwifery appointed. A third type of violation of the voluntary principle consists in the innovation of adding to the managing bodies, representatives of the working classes, or of the contributory insurance groups.

In all these three respects, therefore, the voluntary principle has been sacrificed, maintenance has been received from the State, from the municipal authorities, from insurance schemes, and from the patients themselves. An increasing proportion of the medical staff, including even the visiting staff, has been paid. The managing bodies have been altered in their character by the inclusion of those members who represent the recipients with those who represent donors.

Failure of the Voluntary System.

No one would seriously complain, however, about this sacrifice of the original ideals of voluntaryism if by this means adequate efficiency had been attained. But this is not the case, and every year during which energy and money are spent in trying to save the voluntary system our hospitals are being outdistanced by those of more progressive countries.

The failure of the voluntary system may be described under four headings :—

1. *It has failed to develop in proportion to the needs of the community.*—Only about 30 years ago all serious medical, surgical, and midwifery cases among the poor were dealt with by the voluntary hospitals. Now a very large proportion—probably nearly 50 per cent.—have to be treated by the municipal or poor-law hospitals. The 600 beds provided by the Royal Infirmary and the General Hospital in this city of Bristol have had to be supplemented by 600 beds at Southmead—a building of more modern construction and better site than are possessed by either of the voluntary institutions. It would seem rather futile to argue as to the relative merits of the poor-law and the voluntary hospitals. It is no longer a question as to whether we need have the former. They are here, they are increasing very rapidly in size, quality, and organisation, whilst the voluntary hospitals have had almost to stand still, the mere struggle for existence absorbing all their energies.

2. *It has failed to meet the growing need of the middle classes.*—Dr. Graham Little has admitted this so fully that I cannot do better than quote his own words :—

> "The waiting-lists for admission to these institutions (voluntary hospitals) are getting ever larger . . . a class is clamouring for treatment in voluntary hospitals which was never willing previously to consider such treatment as a possibility . . . the necessity to meet the demand of the middle class for hospital service has been very insistent."

The well-to-do and the middle classes are expected to support the poor-law hospitals by rates and taxes and to maintain the voluntary hospitals by free gifts, and having done these two things they must then seek treatment themselves in less well-equipped nursing homes and pay for this themselves. The bare recital of such a state of things will surely make us realise that there is something wrong with our hospital service.

3. *It has failed to maintain an adequate standard in regard to sites and buildings.*—I am speaking now of the country in general and our city in particular. Of course, there are a few favoured places where the voluntary hospital has been recently modernised, such as St. Thomas's or King's College Hospital in London, and also in those places where voluntary effort has been concentrated upon one main hospital such as Edinburgh, Leeds, and Manchester these institutions are first-rate. But in most places, including Bristol, the voluntary hospitals have had to be content with patched-up buildings on unsuitable city sites.

4. *Most important of all, it has utterly failed to coördinate the hospital services necessary for the community.*—This, to my mind, is the very crux of the whole matter. The voluntary hospital is an independent unit—an irresponsible charity, which is answerable to no one and responsible to nobody so long as it can pay its way. A hospital may be thoroughly bad from foundation to roof, bad in site, bad in management, but so long as its managing body can appeal to sentiment by such cries as "save our hospital," "we have treated in the last year so many thousand in-patients and so many thousand out-patients," and so long as clergy, leaders of politics, or society will lend their assistance in obtaining money then there is no power by which such a hospital can be replaced or reformed.

In the case of hospitals of essentially good quality the main object of the management is to make an independent hospital unit, rather than to coöperate with other units in providing a perfect hospital service for the community. A perfect hospital service must imply providing for all classes and all diseases. It must provide special apparatus, special departments, special practitioners, and special nurses of the best quality and in the right proportion to the need that exists for each of these things. This can only be done by unification and coöperation and can never be accomplished by multiplying special departments at many hospitals with unnecessary multiplication of apparatus and wasteful overlapping. Again and again different people, business men, hospital staffs, and university authorities have declared that amalgamation of the hospitals in Bristol is urgently needed for efficiency, economy, and progress, but the independent conservatism of the voluntary hospitals has each time proved to be an insurmountable obstacle to this reform. If the voluntary hospitals refuse to put their own house in order then they must not complain if some outside force—medical and public opinion—arises which will take their heritage from them.

Unjustified Claims.

The upholders of the voluntary system are wont to make many claims on its behalf which cannot fairly be sustained. The newspapers in particular are never tired of writing about our "wonderful voluntary hospital system" as though its superiority were universally acknowledged. But this is far from being the case. In other countries, such as Germany, Holland, Scandinavia, Canada, and America, there is not the slightest disposition to adopt the principle of voluntaryism, and what is much more significant, our own people, whether medical experts or laymen interested in hospital management, when they go to these countries to see other systems come back filled with misgivings about our own system, and they say quite plainly that if this system is not soon mended it will have to be ended. Prof. Berry, travelling in Canada and the States on behalf of Melbourne University, and Mr. Leaney, house governor of the General Hospital, Birmingham, going over the same route to advise about the new Birmingham hospital scheme, are notable examples of men brought up with knowledge and bias in favour of our voluntary system, who have been completely convinced by what they have seen, of its inadequacy.

It is claimed that the voluntary system of management is good and that it could not be sacrificed. Now this, too, I think is wrong. That the disinterested philanthropy of hospital managers is beyond all praise no one will dispute. But that the constitution of the managing bodies allows for the necessary expert knowledge of the needs of modern science, or of the needs of the community in respect to hospital service or medical education is open to question.

In the first place the majority of hospital managers are busy men, who only devote an occasional hour to hospital work. They have no previous education in medical or hospital things and neither previous to election nor during time of office do they have any experience of any other medical institution than that which they are serving. It seems, moreover, rather invidious to signal out the managers of voluntary hospitals for special praise on account of the fact that they do their work without any emolument.

because exactly the same can be said of those who serve on the guardians, the county or municipal councils. The board of management of a voluntary hospital, the board of guardians, and the municipal council can all be given unstinted praise for hard work done without fee. But every one of these bodies is defective in regard to expert knowledge, and most of all in their outlook and interest being narrowed to the management of their own institution whilst they take no responsibility for the hospital service of the community at large.

Voluntary hospital committees are actually engaged for most of their time on petty matters of detail relating to housekeeping or personnel, and any little economies that may result from their supervision is nothing compared to the terrible waste of men, women, and material brought about by the overlapping of many small hospitals doing similar work.

It is claimed that the voluntary hospital fosters research. It would be much truer to say that research goes on under much greater difficulties in our own hospitals than in the case of hospitals abroad. Dr. Little actually quotes the case of Lister, yet it is notorious that Lister did his work under the greatest discouragement in the various voluntary hospitals in which he worked in this country, but on the other hand his discoveries were quickly appreciated and systematically applied abroad; and that antiseptic surgery was in full practice in other countries when it was fighting for recognition here.

At the present time medical research is provided in our teaching hospitals in a far smaller proportion than is the case in America, our own Colonies, or in the various European countries. And, moreover, such scanty provision as does exist is chiefly made by the universities, which are themselves State-aided. Our voluntary system and the exploitation of the medical profession by the hospitals make it very difficult for young men to give themselves wholly, or partly, to medical research. In fact, it is almost impossible for a young man to get on to a good hospital staff unless he has private means, or unless he is prepared to spend all his time in coaching or some other remunerative work. How is it possible in the first place to have the choice of the best men, or to give such men as we can get, an opportunity of doing research work?

Those who uphold the voluntary hospitals are accustomed to speak of State hospitals as though such "bureaucratic" systems necessarily check research. The note of scorn is most profound when referring to Army hospitals or poor-law institutions. And yet in sober fact the Army system during the war, in some respects at any rate, did stimulate research, team-work, and organisation of treatment in a way which the voluntary system in peace time has been unable to imitate or even continue. Take, for example, the treatment of fractures. This was organised and managed by segregation of cases, continuity of treatment, and team-work, both among doctors and nurses, so that lives and limbs were saved, good methods were standardised, and young men were taught. I would venture to say that though no war exists to-day, yet a very strong case could be made out in London and all our big cities for an organisation of fracture treatment similar to that we were taught by the war. It should be decided how many beds and what sized out-patient department are needed for each city or district, probably nothing less than a 200-bed unit would be worth considering. Exactly the same improvement in results to the patient and teaching to nurses and practitioners would occur as did during the war, and yet who can be sanguine enough to imagine such a reform taking place in the present attitude of our voluntary hospitals?

The large poor-law or municipal hospitals are clearly indicated as most suitable fields for all kinds of organised treatment and medical research, if they can be provided with a staff on a more adequate scale. As a matter of fact, judged by the pages of the *British Journal of Surgery*, the staff of our poor-law hospitals do even now contribute to surgical research and literature more than the staff of many of the voluntary hospitals.

English nursing is claimed as the peculiar product of our voluntary hospitals. Dr. Little says: "We owe it to the voluntary hospitals that Sairy Gamp has been finally dispossessed by Florence Nightingale." Could any statement be more inaccurate or misleading? Surely Sairy Gamp was just as much a product of our system as Miss Nightingale, in fact more so. Miss Nightingale realised the defects of our nursing methods, but in order to find some better ideal she had to go abroad to Germany and France where she worked under certain religious orders. She came back to this country prepared to found an Order of Religious Nurses, but the Crimean War occurred and gave her the opportunity of developing her great genius. In establishing her ideas she worked chiefly and primarily with the army authorities, and again, therefore, we have to admit that it was not the voluntary system but a State organisation which enabled Florence Nightingale to demonstrate and perfect her nursing methods.

That the voluntary system ensures a specially kindly relation between the medical staff and the patient, and it is stated or implied that in other hospital systems and in other countries this relation is less happy. We are told a great deal about such vague things as "atmosphere," "sentiment," "humanity," and the "spiritual aspect." But most of these vague statements are either irrelevant or untrue. Most of us have served in voluntary and military hospitals at the same time and we know that not only was the relation between our patients and ourselves just as cordial at the latter, but also that patients greatly preferred being in the military to the civil hospitals.

In this connexion I must quote a sentence from Mr. Leaney's article, which ought to be read by all interested in this subject:—

"I will go further and say that I do not think that we show as much consideration for our patients in our organisation as we ought, and not as much as I have seen myself in other countries." [2]

There are at least two points on which our voluntary hospitals have much to learn in this very respect from hospitals in other countries and especially from those in America and Canada. In the first place, the out-patients ought to be given much greater consideration in regard to the matter of waiting for hours to see the consultant. Each ought to receive an appointment card specifying a given time so that as in the case of private consultations he should not have to wait for a long period. And again the home life and social circumstances of the poor patient ought to be a matter of organised inquiry, so as to ensure proper after-care and a follow-up of results.

Essentials of a Good Hospital System.

In conclusion the following may be briefly formulated as some of the essentials of an efficient hospital system:—

1. Management of the hospitals by the people for the people, including all classes of the community who are to use them.

2. Maintenance by an extension of the present Insurance Act. Maintenance of any who do not come under the Insurance Scheme to be paid for by themselves or by the county or the municipality.

3. Capital outlay for land and buildings to be provided for (*a*) by the use of existing buildings and sites, the sale of which in many cases would produce large sums of money and enable better sites to be obtained; (*b*) by State and county grants.

4. Effective fusion, coördination, or coöperation between all hospitals of every kind and variety in given areas. This fusion must be under the control of the Ministry of Health.

5. State aid without State control. This principle is already well established in the maintenance of many of our universities.

[2] On the Future of the Voluntary Hospitals. By A. H. Leaney, House Governor, General Hospital, Birmingham. The Hospital Gazette, January, 1928, p. 9.

OCCUPATION, HEALTH, AND MORTALITY

IN THE LIGHT OF THE REGISTRAR-GENERAL'S DECENNIAL SUPPLEMENT.

ONLY by reference to records, which usually take the form of mortality statistics, can the influences exerted upon the human frame, for good or for evil, by climatic conditions, by social status and customs, or by occupational environment, be disclosed and evaluated. Difficulty, however, arises in amassing sure and certain facts from which to draw deductions; but, on the other hand, the "average" human body is a delicate and reliable reagent, most proper for mankind to study. Comparison of race with race, of country with country, of urban with rural peoples, or of town with town, each uncovers differences of interest and importance. But no comparisons reveal such contrasts, challenging attention and declaring causative risks, as appear when social classes are envisaged and occupations are investigated.

This statement is borne out by a decennial report just issued by the Registrar-General[1]; it is the eighth since the series was started by Dr. Farr in 1851 and deals with the mortality of males in the years 1921–23 in five social grades and in different occupations in England and Wales. It differs from its forerunners in presenting, as well, the fertility of these men and the mortality of their infants; further, it distinguishes occupations for the first time on purely occupational lines, so accentuating the real differences between the mortalities. No longer is a group, exposed to some risk, diluted by others, industrially related, but not subject to the risk; for example, managers are no longer included with operatives; coal hewers are separated from others employed underground or at the pithead; and grinders of knives, with exposure to silica dust arising from their sandstone wheels, are kept distinct from the cutlers who mount and polish the articles. In this last instance the composite cutlery group in 1910–12 showed a mortality 63 per cent. in excess of the average; now the grinders alone exhibit an excess mortality of no less than 230 per cent. Another change is that the standardised "Comparative Mortality Figures" are calculated for ages 20–65, instead of for ages 25–65 as heretofore. The standard used is that population —109,296 males—which yielded exactly 1000 deaths at the death-rates for different ages prevailing amongst all occupied and retired civilian males in 1921–23. These changes forbid the institution of comparisons between the C.M.F.'s of this report and those of previous occupational supplements. Continuity, of necessity, has been sacrificed; much more, however, has been gained than lost. Still we may hope that in future reports further changes will be avoided.

A special feature has been made in the Supplement of mortality by social grade, passing from Class I. to Class V. in descending order of refinement. At every age Class I. has the advantage; while the handicap of Class V. is greatest in middle life, 35–45, when the influence of adverse occupational conditions is at a maximum and appears to exert a selective influence in eliminating the unfit. Certain causes of death, such as phthisis, have long been known to be correlated with social grade, and the new figures confirm earlier inquiries, but they also exhibit statistical evidence of other associations hitherto unsuspected. Perhaps the most remarkable of these is concerned with cancer, deaths from which are tabulated by site attacked. The influence of coal-tar products and shale oils in originating skin cancer among chimney-sweeps, pitch-workers, briquette-makers, and mule-spinners is again manifested; but the fact is new that cancer affecting the lip, tongue, mouth, jaw, onwards to the stomach and ceasing at the pylorus, shows for each site mentioned, although less definitely as we proceed from lip to pylorus, an incidence increasing steadily from Class I. to Class V. Below the pylorus, cancer attacks the social classes without discrimination. The upper alimentary tract can be largely influenced by food and drink, but the particular power developing cancer here more in Class V. than in Class I. remains unrevealed. Cancer of the tongue and œsophagus are related to the incidence of chronic alcoholism; but evidence is lacking of any association between alcoholism and cancer of the stomach. Similarly no facts are found to support the suggestion that most gastric cancers arise from ulcers. The data relative to cancer of different sites are given in full and carefully discussed; a few may be quoted:—

—	Ratio of cancer of—		
	Tongue.	Œsophagus.	Stomach
All occupied and retired males	1000	1000	1000
Social class—			
1. Upper and middle ..	480	763	597
2. Intermediate	733	907	820
3. Skilled workers.. ..	947	1041	997
4. Intermediate	1000	876	1058
5. Unskilled workers ..	1653	1299	1295

A somewhat curious fact is reported that nearly all the occupations noted as of excessive skin cancer mortality—ascribable in practically every instance to contact with fire or fuel stuff of some kind—record a cancer mortality for sites other than the skin also in excess of the average. Is this why Prometheus was punished for his gift of fire to humanity?

In contradistinction to the above and to phthisis stands diabetes, which affects chiefly the classes provided with the financial means of over-eating and under-exercising. But early and late diabetes are statistically different; at early ages hereditary defect in the pancreas may be the cause, while in later life overload breaks down normal machinery for utilising carbohydrate food. An unexpected coincidence is stressed—viz., that glass-blowers, skilled glasshouse workers, and glass-workers not in the glasshouse, all exhibit excessive mortality from diabetes, none of which occurs at ages over 65, and hence may be significant of some unrecognised occupational influence. Associated with diabetes stand appendicitis and cirrhosis of the liver, which latter varies in proportion to the financial means of obtaining so expensive a luxury as alcohol. Broadly speaking, these diseases cost money; the occupational groups which prove exceptions to the social grading are publicans, brewers, barmen, and cellarmen. Truly taxation, if not legislation, seems capable of imposing some degree of sobriety. Contrary to common belief, occupational risk is seldom expressed in circulatory mortality; but such mortality is an outstanding feature of the textile trades, both woollen and cotton, and it is associated with chronic nephritis. In fact, the conditions of work in textile mills are disclosed as promoting degenerative changes of the kidneys, heart, and blood-vessels. A hint at possible causation may lie in high mortality from circulatory disease among cotton weavers in dry sheds, but low mortality among those working in wet sheds. Myocardial disease is highest where silica risk is present, which in its turn is a cause of bronchitis and this, again, is positively correlated with chronic nephritis; thus silica dust—an essentially occupational risk—is exhibited as exerting a degenerative influence on other tissues than the lungs. Bronchitis considered alone, is more closely associated with social status than any other cause of death, with C.M.F.'s varying for the five classes from 12·7, to 27·2, to 46·5 to 59·4, and to 87·4 respectively. Causative influences of this disease are found in most forms of dust and also in exposure to artificial heat and moisture, as well as in the atmospheric conditions of the north as compared with those of the south.

The section of the report devoted to discussion of the 178 separate occupations, for which mortality

[1] Registrar-General's Decennial Supplement. 1921. Part II., Occupational Mortality, Fertility, and Infant Mortality. London: H.M. Stationery Office. 1927. 7s. 6d.

ata are provided in excellent tabular form, is too engthy for adequate summary. Agriculture, as lways, presents a favourable picture. Coal-mining is xtensively considered, both with regard to work done nd to coal-field. The coal-miner appears to have enefited in the last ten years less than others, but his ıortality is still favourable. Again Lancashire ollowed by South Wales is found with higher ıortality than other coal-fields, but the difference is ess than in 1910–12. Special attention is paid hroughout to manifestations of recognised risks, such s dust among tin-miners and iron-miners, stone-asons and potters, cotton-strippers and others; and ıtense heat among gas-stokers, puddlers, and glass-orkers. The new figures relating to fertility again how birth-rate increasing from the highest to the owest in the social scale, a characteristic pheno-ıenon of our own generation. Infant mortality is ound highest where the birth-rate is highest, but has fallen remarkably for all grades of the com-ıunity in recent years, and now varies from only 8 for Class I. to 97 for Class V.

MEDICINE AND THE LAW.

Illegal Operation: Verdict of Manslaughter.

On Jan. 27th Charles Jackson Palmer, aged 59, escribed as a medical electrician, was found guilty t the Central Criminal Court of the manslaughter f Mrs. Goldsmith, a young woman of 21, who had one to his consulting-room in Upper Brook-street or treatment on returning from her honeymoon. he prosecution alleged that her death was due to the nlawful injection of a fluid made up of soap and ater, injected for the sole purpose of procuring bortion. The accused stated that the deceased came o him for electrical treatment for anæmia and ervous debility; he denied that he knew that Mrs. oldsmith was pregnant; he said he was giving her lectrical treatment when she suddenly sat up, lenched her hands, and collapsed. He told the olice inspector that the treatment consisted of lacing a pad down the spine and inducing an lternating current through the body in the region of he abdomen. Dr. H. B. Weir, who made the post-ıortem examination, said the deceased was a erfectly healthy woman. On opening a portion of he body a soapy fluid began to escape; he saw ıething suggesting a slight abrasion. Sir Bernard pilsbury said the fluid was a strong solution of soap nd water; he drew the conclusion that the abrasion as produced by the nozzle of a syringe a few minutes efore death. Both these witnesses were of opinion hat the cause of death was shock due to an injection f fluid. The defence sought to discount these pinions and claimed that the evidence was consistent ith the view that death was the result of electric hock; if there was soapy water in the body, the dead oman had perhaps placed it there herself. After he jury had found the accused guilty, the Lord Chief ustice described the conviction as based on evidence o clear as to be quite overwhelming; it "approached he certainty of mathematical demonstration." A olice inspector reported that there was no previous onviction against the defendant; for some years he ad conducted a genuine medical electrician's business mong well-to-do people, but during the past 5 months the police had received information uggesting that he had been a party to illegal opera-ions; his premises had on that account been equently visited by inspectors. Lord Hewart sked questions during the case as to the by-laws ıade by the London County Council under its eneral Powers Act of 1920 for regulation of massage nd special treatment establishments. These appear o contain valuable provisions, but it is for considera-ion whether some further and more vigilant measure not possible to restrict the conduct of premises ke those of Palmer as a place where criminal bortion can be practised with such appalling results.

On Jan. 31st Lord Hewart passed a sentence of seven years penal servitude and ordered Palmer to pay the costs of the prosecution. Persons, said the Lord Chief Justice, to whom clients resort for the purpose of illegal operations, undoubtedly subject those clients to very grave risks; "it is right that all of them, wherever they may be in this country, should understand that they incur grave risks themselves."

Pasteurised Milk.

In 1922 Parliament forbade the offer for sale and the advertisement or description of milk as "pasteurised milk," except under licence given by the Minister of Health or granted with his authority under a statutory order. Licences could be granted on terms and conditions prescribed by such order. The subsequent Milk (Special Designations) Order of 1923 dealt inter alia with pasteurised milk and enacted as one of the conditions that, on a sample taken after pasteurisation and before delivery to the customer, the milk should be found to contain (in samples taken after the year 1923) not more than 100,000 bacteria per cubic centimetre. Our contemporary, the *Medical Officer*, reports what is perhaps the first of the prosecutions for breach of this condition. A Wandsworth firm was prosecuted at the Kensington Petty Sessions for selling "pasteurised" milk not of the stipulated statutory standard, a sample (submitted to the Clinical Research Association) having shown bacteria to the number of 323,333 per cubic centimetre. It was stated for the prosecution that two other samples taken might equally have formed the subject of proceedings, and that the lids of the churns from which the samples were taken did not satisfactorily exclude rain and dust. The magistrates found the offences proved and fined the defendant firm (which had not appeared) £5 and £10 10*s.* costs. There was a second summons on which a further fine of £3 was imposed. This was for selling in Kensington without a Kensington licence in breach of a condition specified in the licence. The firm had a Wandsworth licence for selling pasteurised milk, but this did not authorise sale outside the Wandsworth area except by way of wholesale distribution.

Death from Borax Poisoning.

Recently at an inquest at Luton on the death of an infant, 18 days old, Dr. J. Birch stated that the post-mortem examination showed death to be due to borax poisoning. The symptoms, he said, could have arisen from the use of honey and borax or glycerine and borax, a jar of which was produced in court. Dr. Birch criticised the use of this substance as dangerous especially when dispensed as a remedy for thrush—usually administered by smearing it on the gums of the infant. He stated that a quarter of the amount given to this baby had been known to be fatal to adults. He had known the danger of this preparation all his professional life and had always forbidden its use. He considered it ought not to be given in the British Pharmacopœia in its present strength.

Injury Caused by Hair-dye.

Actions are not infrequently brought against hair-dressers for damages for dermatitis caused by the application of hair-dye. They are based upon allegations that the hairdresser has been negligent, or alternatively upon breach of contract and warranty. Such an action was lately brought against an Oxford-street hairdresser who appears to have employed a dye containing 30 per cent. of para-phenylene diamine. His practice was to exhibit a printed notice disclaiming liability for the ill-effects of his hair-dyes; the notice stated that about two persons in a thousand suffer ill-effects; "as it is impossible to know these few without a test, we are willing to give this free trial on the customer's own responsibility." The plaintiff, who wanted her hair dyed blue-black like that of a friend of hers who had recently been so treated, was given a preliminary test. Dye was applied to a patch of skin behind the ear

the size of a sixpence. The result, according to the plaintiff, was dermatitis of the scalp, inflammation of the left ear and of the neck and chest, swelling of the eyelid, insomnia, shock, and nervousness. Mr. Justice Horridge left it to the jury to say whether, in all the circumstances of the case, the plaintiff had received adequate warning of the risk she ran in having the test applied; if she had had such a warning, they should find a verdict for the defendant. This they proceeded to do forthwith, without leaving the box, and judgment was entered for the hairdresser with costs.

Health or Justice?

The learned Recorder of Chichester, at a lecture given to the Royal Institute of Public Health which was reported in THE LANCET last week, gave his opinion that no change should be made in the legal rule which requires a doctor to disclose confidential details concerning his patients. Lord Justice Atkin, however, expressed a different view at the close of the lecture; he frankly stated that in some cases—notably those connected with venereal disease—the claims of public health far outweighed those of justice, and he favoured a change in the law. The Lord Justice provided a fresh argument in this controversy by referring to the secrecy with which certain evidence of official matters is treated. The solicitor's privilege is defended because it is in the interests of the administration of justice; the doctor's privilege is refused because it conflicts with the administration of justice; and yet the courts allow facts to be withheld—if, for instance, they concern the technical details of the equipment of our fighting services—without any reference to the administration of justice whatsoever. In the past few weeks there has been a prosecution under the Official Secrets Act of two spies, who have received severe sentences; part of the evidence was given behind locked doors. There has also been an application in the police-court concerning the ownership of certain naval documents, and again the proceedings were partly carried on in camera. May it not be just as much to the interest of the State to withhold facts dealing with a man's health as to withhold facts dealing with the construction of a submarine?

SOUTH AFRICA.

(FROM A CORRESPONDENT.)

Dengue in Durban.

DURING the first half of 1927 Durban suffered from a remarkable epidemic of dengue fever, the number of cases in the town and its vicinity being estimated at about 50,000. At the request of the town council Dr. A. J. Orenstein, of Johannesburg, has submitted a report on the measures that should be taken to eliminate mosquito-breeding and thus prevent the disease. In this report he says that it is now established with reasonable certitude that dengue is transmitted by *Aedes egypti*, more commonly known as *Stegomyia fasciata*. This mosquito invariably breeds in collections of water near human habitations, its flight is very limited, and it may safely be said that under ordinary circumstances it does not travel more than 100 yards. The larvæ are most commonly found in artificial receptacles, both indoors and outdoors, and will develop in very small collections of water—e.g., in tin cans or broken bottles, in ewers of water in unused guest rooms, in water-tanks, water-barrels, and holes in trees. The larvæ can remain submerged for several hours, and consequently may be difficult to detect in fairly large collections of water, such as rain-water tanks. The eggs are very resistant to unfavourable conditions and may remain dry for months and yet, when placed in water, hatch out healthy mosquitoes. The adult mosquito will, under favourable circumstances, survive for several weeks.

It used to be considered, says Dr. Orenstein, that *Culex fatigans* transmitted dengue, but experimental work seems to have disposed of this theory. Stegomyia is almost certainly the sole danger, and its habits c breeding are consequently of great importance i considering the preventive measures. As it appear that a very large portion of the European populatio of Durban and its vicinity were attacked by dengu during the first half of 1927 there is good reason t believe that an outbreak on a large scale is improbabl in the near future among the European population inasmuch as it has been shown by Siler, Hall, an Hitchens that the disease conferred immunity i 58 per cent. of cases, and modified towards mildnes subsequent attacks in the remainder. An outbrea might, however, occur among the native and coloure population, who apparently were not affected as muc as the European population by the last epidemic, an an outbreak of minor magnitude might occur amon the European population not attacked in the las epidemic.

Dr. Orenstein does not think that dengue should b made a notifiable disease, but he suggests that th medical officer of health should circularise the medica practitioners of Durban to ensure (*a*) that all case should, for the first three to five days of their illness be carefully protected by mosquito nets; and (*b*) tha the houses of such cases be searched for adul mosquitoes and for mosquito-breeding, with a view t its elimination. He recommends that the municipalit should offer to provide on loan mosquito nets fo patients and for the personnel of the mosquito search for "Protection of the sporadic cases against mosquit bites . . . is the best and most promising measure o preventing an epidemic of dengue."

It is suggested that the following amendments b made in the public health regulations:—

(*a*) No tanks, wells, barrels or receptacles of any kind fo the collection or storage of water shall be permitted excep in those districts which are without a public water-supply When such tanks, wells, barrels, or other receptacles for th collection or storage of water are permitted, they shall b made mosquito-proof to the satisfaction of the medica officer of health. Wells, where permitted, must be fitte with an approved pump.

(*b*) The throwing or keeping of tins, bottles, broke crockery, or any other object that may hold water an thereby become a breeding-place for mosquitoes, in an street, yard, alleyway, or any premises or property, whethe occupied or unoccupied, constitutes an offence.

(*c*) All premises, whether occupied or unoccupied, must b kept in such a condition as to prevent mosquito-breeding and the medical officer of health may give notice to th owner or occupier of such premises requiring him to correct within a definite time-limit, the conditions as specified i the notice. Failure to carry out the instructions containe in the notice shall constitute an offence.

(*d*) Roof gutters shall be so planned and constructed as t be self-draining and remain dry between rainfalls. Upo due notice from the medical officer of health, which shal specify a time-limit, the owner or occupier of the premise shall remove or repair roof gutters which hold water an might give rise to mosquito-breeding.

(*e*) If any owner or occupier refuses to carry out th measures specified in any notice under these regulations, o fails to do so within the time-limit imposed, the loca authority may, by persons duly authorised thereto, carr out such measures. The costs incurred in so doing shall b recoverable by the local authority from the person upo whom the notice was served.

Dr. Orenstein recommends that special inspector be detailed for work against stegomyia; it would b their duty systematically to inspect premises fo breeding-places, especially during the warm season The large swampy areas in the vicinity of Durba present difficult problems of mosquito control Without more data Dr. Orenstein is not prepared t suggest definite methods of permanent control, bu proposes an experiment on a small scale in two area where cattle could be kept out by fencing, sunflower could be planted, and collecting pools could be arrange at the lowest point, with clear banks, for any excessiv water. This might, he thinks, lower the surface wate sufficiently to diminish mosquito-breeding ver considerably. At present larvæ are controlled i swamps and ditches by means of crude oil, but i several instances he found larvæ where oil had bee recently applied, this being due either to the o

being blown away by the wind or to the film being broken by vegetation or dry twigs. A great many mosquito-breeding areas could, he thinks, be more economically treated by the application of some cheap emulsifying larvicide.

Retirement of Port Natal Health Officer.

Dr. H. E. Fernandez has retired from the post of port health officer at Durban, Natal, after a service of 32 years. He has seen Durban develop from the days when there was only a depth of 17 feet of water on the bar at the top of high tide to what it is to-day—when vessels of the deepest draught come inside to the wharf.

Bilharzia in the Transvaal.

Remarkable success has been achieved by the pioneer camp established at Rustenburg School for children suffering from bilharzia. Sixty patients drawn from 25 different schools in the district—which is particularly pestered by the disease—have been undergoing treatment at the camp, and are reported to have been completely cured in less than a month after their arrival. The Director of Sanitation for the Rand Mines submits that it is imperative for the authorities of the Provincial Council and the Union Government to coöperate in establishing similar camps throughout the Transvaal.

The Carnegie Corporation of New York has drawn up a five-year programme of grants in aid of scientific research in the Union of South Africa. The sum of £1500 is to be used in investigating the Bantu mentality, whilst £4000 will be set apart for a study of the "poor white" problem. The total amount to be expended will be £100,000, and £18,000 is to be used for encouraging the exchange of visits between South African and American scientific and educational authorities. Some of the funds will be devoted to social and medical work in East Africa.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Diabetes in Germany.

IN the course of a recent address to the Society for Insurance Medicine Dr. Ullman drew attention to the increase in diabetes throughout the world, an increase most obvious, he said, in the United States. The late war caused a general diminution in the disease; thus in Berlin the mortality per 1000 rose from 1·0 in 1900 to 2·3 in 1913, but in 1919 had fallen again to 1·0. Since that time there has been another steady rise, bringing the death-rate to 1·8 per 1000. The age-period at which diabetes most commonly shows itself is from 40 to 45, and it attacks especially those classes whose work involves much mental strain. In America there is a saying that if prices on the stock exchange fall the amount of diabetes rises. The mortality is higher in towns than in the country, and Dr. Ullman considers that no race is especially liable to be affected, the apparent racial differences being actually dependent on varying habits of life. Up to 35 years of age both sexes are equally prone to the disease, but afterwards the mortality among males increases owing to the exertion and excitement of their work. Now that women are working more than formerly the difference between the rates for the two sexes is diminishing. It has not yet been ascertained whether diabetes is growing more severe in type.

Infectious Diseases in Berlin.

The last two years have seen a considerable increase of diphtheria in Germany, and especially in Berlin, where the number of cases is three times as great as in 1925. But, as Prof. Seligmann, head of the Berlin Municipal Laboratory, points out, the record of the last five years is on the whole a good one; diphtheria, indeed, reached its minimal incidence in 1924, and it may be hoped that the increase is only transient. 500 cases were notified in Berlin during September and October, 1927, as compared with 200 in the previous year, most of them being in the east and north-east parts of the city, which are thickly populated by poor people. School-closure is sometimes adopted by the municipal educational authorities, but they do not approve of this measure as a rule as it does not seem to be very effective and may lead to infection being spread more widely. The clinical course of the disease has grown worse, and the case-mortality has been higher in Germany than elsewhere. The prevalent organism seems to be of a specially malignant type; possibly, too, the resistance of the population has been lowered by the privations of the war and of the period which came after it. To combat its consequences antitoxin is given gratis to indigent families, and pamphlets warning parents against negligence are distributed in the schools.

Last year's figures show that the incidence of scarlet fever and measles in Berlin was much as usual. Notifications of infantile paralysis, of which an epidemic occurred at Leipzig and elsewhere in Germany, are seen to have increased but little. Dysentery and typhoid fever have been kept under control by regulation of the water and milk-supply, but meat-poisoning and paratyphoid have been on the increase. If the people of Berlin would refrain from eating raw meat in the form of "beefsteak à la tartare," the amount of poisoning would diminish.

The Soft Palate in Diagnosis.

In a paper read before the Berlin Medical Society Dr. Neuda pointed out that examination of the soft palate will often give useful information about general as well as local diseases. The colour of the palate may be altered, showing either hyperæmia or anæmia; it may look œdematous, and the junction with the hard palate may disappear or else become more obvious. Increase of fat in the soft palate suggests metabolic disorder, and also occurs in cancer of the stomach. In duodenal ulcer the soft palate is hyperæmic; large spots of hyperæmia indicate recent syphilis, whilst small spots show congenital syphilis. The palate is yellow, of course, in diseases of the gall-bladder.

SCOTLAND.

(FROM OUR OWN CORRESPONDENT.)

Edinburgh Health Week.

THE Edinburgh Health Week has included a full programme of medical and hygienic conferences and demonstrations. The Society of Medical Officers of Health, the school medical officers, and those lay and medical men and women associated with child welfare and maternity service, have all found a convenient platform and good audiences. But the outstanding feature of the week has been the health and hygiene exhibition in the Waverley Market. Edinburgh is very fortunate in having so fine an exhibition hall in a position so central. The daily average of visitors even in the first few days approached 10,000, and the exhibition deserves their patronage. It includes most of the leading departments of civic activity affecting health and the prevention of disease. The tuberculosis sections under Dr. John Guy, the children's sections under Dr. Leonard Findlay, and many of the others attracted continuous crowds. The cookery exhibits and demonstrations under the Atholl Crescent School of Cookery were among the best of the relatively "lay" sections. Dr. William Robertson, the medical officer of health, and his very active collaborators are to be complimented on the success of a first-class exhibition. It is the largest demonstration of civic hygiene that the Edinburgh Corporation has, in its official capacity, organised within the last 30 years.

Industrial Health Education Society.

This society took advantage of the Health Week to organise a meeting in the Usher Hall. In numbers the meeting was not large, but all those present were individually interested. The Secretary of State for Scotland made a telling appeal for support and encouragement. Men of all parties, creeds, and classes

were joined together for one common purpose, and in that appeal to the general citizens of the country they would be repaid a thousand-fold if all would take action personally in their own spheres. Sir Thomas Oliver, in his usual lucid and effective way, gave a few good illustrations of how preventive medicine had been applied to occupations and how "phossy jaw," lead poisoning, and other conditions had been reduced the moment detailed scientific attention was given to the manufacturing and working processes. Mr. William Graham, M.P., emphasised the value of the work being done by the Medical Research Council and the Industrial Fatigue Research Board. It is gratifying to learn that the lectures by medical men for the society now run into hundreds a year and the demand is steadily increasing. Scotland has the credit of originating this society.

The Cream Regulations.

The new Cream Regulations seem to have caused much more concern to Scottish than to English producers. The complaints of the trade are persistent, and it is disappointing to note that producers and those that express their case in print seem to believe that the English Ministry of Health has jurisdiction in Scotland. They seem unable to learn or to believe that on the day that the Ministry issued their Preservative Regulations for England and Wales the Scottish Board of Health issued a parallel and independent set for Scotland. Scotsmen are never tired of boasting about their independence, but they seem to prefer government from London. There is, however, one really important point: in Scotland there never has been, as in England, any regulation permitting boric acid (maximum 0·4 per cent.) in "double" cream. For all these years, however, the Scottish producers have assumed that they were legally entitled to add boric acid. Now that they are expressly told that what has been the law all along under the Food and Drugs Acts is to be definitely enforced under the new Preservative Regulations, both English and Scottish, they cry out more lustily instead of setting themselves to devise better methods of production, manufacture, storage, and transport. The milk trade is always resentful of interference. Every reform of its methods has to be initiated by smashing blows from without. Probably, as the Scottish cream market is about 50 per cent. English, Scotland may for a time suffer more. But there are some large producers who welcome the new regulations. A point to remember is that these are not aimed at the small or large quantities of preservatives, but at the evil conditions of production that make any preservative necessary. Meanwhile the prosecutions for adding preservatives to "mince meat" are proceeding and there is little doubt that less amounts of unwholesome scraps are finding their way into the mince-heaps.

Public Health Services.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 21ST, 1928.

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 405; scarlet fever, 2007; diphtheria, 1488; enteric fever, 44; pneumonia, 1550; puerperal fever, 53; puerperal pyrexia, 118; cerebro-spinal fever, 5; acute poliomyelitis, 6; encephalitis lethargica, 28; dysentery, 6; ophthalmia neonatorum, 101. There was no case of cholera, plague, or typhus fever notified during the week.

The cases of small-pox were notified from the following 20 counties:—London 2 (Lambeth, St. Pancras), Chester 1, Derby 16, Durham 85, Hertford 11 (Barnet 10, Ware 1), Lancaster 35, Leicester 7, Lincoln, Parts of Lindsey 3, Middlesex 2 (Edmonton 1, Heston and Isleworth 1), Northampton 20, Nottingham 16, Stafford 3, Surrey 1 (Beddington and Wallington), Warwick 28, Worcester 1, Yorks North Riding 14, West Riding 57, Brecknock 12 Glamorgan 27, Monmouth 64.

The number of patients at the Infectious Hospitals o the Metropolitan Asylums Board on Jan. 24th–25th wa as follows: small-pox, 3; scarlet fever, 1798; diphtheria 2526; enteric fever, 21; measles, 1302; whooping-cough 140; puerperal fever, 13 (plus 10 babies); encephaliti lethargica, 70; poliomyelitis, 2; "other diseases," 4 At St. Margaret's Hospital there were 9 cases of marasmus and 18 babies (plus 11 mothers) with ophthalmia neonatorum

Deaths.—In the aggregate of great towns includin London there was 1 death from small-pox, 4 (1) fro enteric fever, 94 (39) from measles, 4 (1) from scarle fever, 21 (5) from whooping-cough, 51 (13) fro diphtheria, 51 (5) from diarrhœa and enteritis unde two years, and 126 (19) from influenza. The figure in parentheses are those for London itself. Th death from small-pox was reported from Bradfor C.B. The fatal cases of enteric fever outside Londo were reported from Brentford and Chiswick, Leed and Sheffield one each. Of the 55 fatal cases o measles outside London, 16 were reported fro Bristol, 7 from Manchester, 1 from Salford, 6 fro Warrington, 4 from Sheffield, 3 each from Tottenha and Derby, while the figures from Glasgow and Dubli for the same week were 35 and 14 respectively. Th number of stillbirths registered during the week wa 291 in the great towns, including 41 in London.

We learn from Dr. J. J. Buchan that up to Jan. 30t there had been three deaths from small-pox of inmat of the North Bierley Institution at Clayton, just outside th Bradford boundary, after their transference to the small-po hospital. They were debilitated subjects, aged 71, 73, an 75 years respectively, all of whom had been vaccinated i infancy.

BIRMINGHAM TUBERCULOSIS DEPARTMENT.

AN article appeared in THE LANCET of Nov. 12t 1927, headed "Tuberculosis in Birmingham," whic contains several statements regarded by the medic officers of the Tuberculosis Department as giving a unfair impression of their work. It appears tha certain of these statements have been misinterprete The fact has been missed that the article was a surve of the position of antituberculosis work in genera and any criticism of the Birmingham methods forme a part of such general criticism.

ROYAL MEDICAL BENEVOLENT FUND.—At th last meeting of the Committee 43 cases were considere and £630 voted to 32 applicants. The following is a summa of some of the cases relieved:—

Widow, aged 56, of L.R.C.P. who died in 1901. Up to 19 relied on boarders for her maintenance, but owing to ill-hea has had to give up this work, and her income is now reduced about £21 per annum from investments. Lives with an ag father, aged 82, who requires constant attention. Has contribute to her own support. Voted £5 pending furth inquiries.

Widow, aged 55, of M.R.C.S. who died in 1905. Apart fr an annuity of £30 per annum from an aunt, is dependent her earnings by needlework. Rent 17*s.* 6*d.* a week, but su lets two rooms for 10*s.* a week. Voted £26 in quarterly inst ments.

Widow, aged 52, whose husband was in the Indian Medi Service and died in 1921. Only income pension of £90 per annu from War Office. Rent at present £52 per annum. One s married, with one child, but out of employment. Asked immediate help and was voted £10 pending further inquiries.

L.R.F.P. & S. 1890, lady, aged 77, who mostly practis abroad. Since 1921 has not been able to do any work and h now come to the end of her resources. At present living w a brother, but writes, "If possible I do not wish to be a burd on him, I should be grateful if the Fund would grant me so assistance, though I am sure you will quite understand I not like to ask for help." Voted £36 in quarterly instalments

Daughter, aged 64, of L.S.A. 1826 who died in 1873. H earned her living for the past 35 years as governess-compani and on having to give up this work was persuaded by frie to take a small house and take paying guests, who promis her £130 per annum; these allowances have been gradua reduced and the amount now received is only £26 per annu On account of failing health the last guest was requested leave, and a friend found this lady penniless and several sm bills owing. The friend raised a small fund to meet immedi needs and writes to the Fund to say that this was being disbur at the rate of 10*s.* a week, but was almost exhausted. Vot £30 in quarterly instalments.

Subscriptions may be sent to the hon. treasurer, Charters Symonds, at 11, Chandos-street, Cavendis square, W. 1.

Correspondence.

"Audi alteram partem."

TREATMENT OF THE MALARIAS.

To the Editor of THE LANCET.

SIR,—The effective treatment of malaria in its various manifestations is being keenly discussed in the columns of the medical press. I have read with interest the leading article in your issue of Jan. 14th, and Dr. Manson-Bahr's comment upon it. I have myself been using plasmochin for some time and am by no means convinced that the results obtained by its use are any better than those obtained by quinine with iron and arsenic. It is admitted that plasmochin alone does not kill the chizonts of malignant tertian malaria, though it apparently does the gametocytes, the crescents. But what is the use of destroying the crescents—apart from preventing anopheline infection—if the rings which produce them are unhurt? The chizonts will simply produce more gametocytes. The proper method is to destroy the former and then no more of the latter will be formed, and those already existing in the blood will soon disappear. It is a case of the goose and the golden eggs over again. The fact that it is necessary to combine the plasmochin with quinine points its own moral.

There is no doubt also that plasmochin is a more dangerous drug than quinine, its therapeutic and toxic doses being very near together. Dr. Manson-Bahr says that toxicity seems to be entirely eliminated by the mechanical combination of plasmochin with small quantities of quinine sulphate, in the form now known as "plasmochin compound." Why this should be is not clear, and that it is not so in all cases is shown by the fact that I have recently had three well-marked cases of cyanosis and one of sickness after the use of plasmochin compound. I do not say that this matters very much, but on the other hand, in certain individuals it might be serious, and it is a danger that one cannot ignore.

It is quite possible, of course, that in cases which seem to resist quinine or even in ordinary cases, a combination of these two drugs will act better than either given alone; but time only and careful observations will show this. The same may be said of relapses. If it can be demonstrated that these never appear after plasmochin treatment, or rather after plasmochin compound treatment, then the combination will be proved to be better than the ordinary quinine and arsenic treatment, and should be generally adopted. I personally have had one doubtful case of relapse, but as the blood was not tested I cannot say this for certain. There is also the question of expense, a very important one of course.

I have also been extremely interested in the recently reported outbreak of malaria in Barbados, and especially so as I was the first to point out, in 1901, that the reason the island was free from malaria was because there were no anopheles mosquitoes present there. I dealt with the question in a paper entitled Malarial and Filarial Diseases in Barbados.[1] I thought it possible that there might be something in the water of the island prejudicial to the development of the anopheles, so I took a supply of this over to St. Vincent, an adjacent island, where *Anopheles albimanus* was abundant. I found that the larvæ of this species of mosquito lived and developed in this quite well and ultimately pupated and became adult insects. In a note on the Absence of Anopheles in Barbados, W.I.,[2] I said: "This indicates that it will be a very serious thing for Barbadoes if by any chance anopheles mosquitoes were ever introduced to the Worthing swamp." This has apparently now happened, 25 odd years since I made that statement.

[1] Brit. Med. Jour., 1901, ii., 687.
[2] Ibid., 1902, i., 200.

Dr. Andrew Balfour,[3] has indicated how the invasion has probably taken place. Small sailing vessels come into the harbour close to the shore, and anopheles brought over by them from some of the other islands must have escaped, bred, and gradually extended their range to what would now appear to be a fairly extensive one. People returning to the island with malarial parasites in their blood have infected the mosquitoes, and so the disease has broken out indigenously. If the excellent suggestion, of making ideal breeding places, artificially constructed, in close proximity to the wharves, made by Dr. Balfour when he visited Barbados some years ago had been carried out, the infection of the island might well have been saved. It has always seemed strange to me that anopheles have not been introduced before in this way, and it is quite possible they have been, but that they have never been able to establish themselves permanently. Their introduction and permanent settlement this time effectively kills the stupid myth that Barbados has enjoyed immunity from them because of the presence of the small fish called "millions" in the different pools of water scattered through the island. Even in my time I could always get two or three species of culicine larvæ in the pools inhabited by these fish, and now the anopheles are holding their own as well.

There is no use crying over spilt milk, however. What is required now is to stamp out the anopheles, and this, though it will be an expensive matter, is a fairly easy one. The collections of water are small and so can be dealt with easily by drainage, oil, &c. It is not clear yet if the larger collections of water, the swamps at Worthing, are infected or not, but, if so, there will be a greater difficulty in dealing with them. Because of the absence of rivers and big swamps and stagnant water generally, there can be no place easier than Barbados in which to conduct an anti-anopheline campaign. Perhaps it would be as well, however, to send out an expert or experts from home to conduct this.

I am, Sir, yours faithfully,

G. CARMICHAEL LOW.

Brook-street, W., Jan. 26th, 1928.

THREE CONCEPTIONS OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—Of the three conceptions of tuberculosis, suggested by Dr. E. Ward in his paper read before the Plymouth Medical Society (THE LANCET, Jan. 21st, p. 125), the Edwardian is surely the wisest and nearest the truth: "A widespread disease . . . *always dangerous . . . when causing symptoms*" (italics mine). It is dangerous to neglect the symptoms in the same sense that it is dangerous to run past a danger signal on the line. Dr. Ward suggests the term "minor tuberculosis" for the disease in those patients who have become infected with tubercle bacilli, but who have sufficient resistance to recover, with little or no treatment. That such cases do exist there can be no doubt, but the point I would like to emphasise is that when signs or symptoms, or both, have made their appearance, the case can no longer, with safety, be regarded as a "minor" one. In the absence of the gift of prophecy, it is not possible to decide whether the resistance will, or will not, continue to hold its own unaided.

Dr. Ward quotes four cases in whom the precautions taken were as follow: 1. "Commonsense precautions." 2. "Became much more careful." 3. "Continued work under observation and an improved régime." 4. "A short holiday and a few adjustments." All these four cases showed definite signs or symptoms. In one case tubercle bacilli were present in the sputum, and in another hæmoptysis had occurred. The result of an expectant policy in these four cases was happily successful; in fact, Dr.

[3] Brit. Med. Jour., Jan. 21st, p. 114.

Ward may be said to have got away with it; but I think every sanatorium worker will agree with me that the risks run were unjustifiable even by the fortunate results.

The other side of the picture is all too familiar. The cases, hopelessly advanced, obviously ill, with small chances of recovery, which are frequently sent, too late, for admission to sanatoria, usually give just such a history as did the four cases presented by Dr. Ward. Unfortunately, that history refers to a period of three, four, or more years ago. The intervening time has seen the gradual and insidious undermining of resistance which should, long ago, have been reinforced by adequate treatment. Interrogation elicits the fact that the onset of the significant signs and symptoms mentioned by Dr. Ward was met by the treatment prescribed by him. The urgent necessity of sanatorium treatment with prescribed rest and graduated exercises, and education in avoidance of infection, was never suggested, but the patient was fatally reassured and encouraged by such advice as "A holiday in the country will soon put you right," "Plenty of fresh air and exercise is all you need," or "Take a sea voyage and forget all about it." So time was lost, and the cases which may then have been minor became very much major.

It is significant that the four cases mentioned by Dr. Ward belong to the professional class. This is the class in which successful results may well be expected. Intelligent, eager to get well and resume work, keen to coöperate in the comprehended restrictions of the régime, its members are usually the most responsive to sanatorium treatment. It is also, unfortunately, the class for which there are least facilities for obtaining wise and informed direction, and which, in consequence, is often allowed to waste the valuable years by a too complacent policy of "Wait and see."

I am, Sir, yours faithfully,

H. O. BLANFORD.

DAMAGES TO BONES AND REPUTATIONS.

To the Editor of THE LANCET.

SIR,—I have read with admiration Prof. Hey Groves's dissertation in your issue of Jan. 28th. The subject on which he writes is a bugbear to the country practitioner living, as he may do, miles from an X ray plant. The difficulty of transit and also of expense (which does not apply to the rich or the fairly well-to-do in the country) is a matter of concern to the farmer or the country labourer, who, we all know, are in rather a parlous state at the present time. The absence of electricity or even gas in many of our country villages render such cases (together with a possible litigation) a veritable nightmare to the doctor attending.

In the country many of the victims of such accidents cannot even afford to pay the medical man in attendance an adequate fee. Much less can they afford the cost of a car to take them to the nearest hospital for an X ray photograph; and again, after a few days, a repetition to see that the parts are keeping their proper alignment. The country man is an obstinate individual. He prefers to be ill at home to lying in a hospital bed, however much he may be told the advisability of it. And yet, in these days, he expects the same treatment and attention. If he does not get it, he maligns his medical attendant, often through the medium of his relatives and friends, from lady bountiful to the village drunkard.

I cannot say to my knowledge that I have myself suffered from such folk, but I know plenty who have. Prof. Hey Groves says, "Efficient portable X ray plant ought to be available whenever needed," and he suggests an ambulance service equipped. This is excellent and ideal. But how is this service to materialise?—I am, Sir, yours faithfully,

R. T. RICHMOND.

SPECIFICITY OF ANTI-CANCER SERA.

To the Editor of THE LANCET.

SIR,—I gather from recent conversations with oth scientific workers that it may save their time as w as mine, and avoid future correspondence, if y permit me to epitomise here my present views as the specificity of anti-cancer sera. With the assistan of Miss A. C. Kohn-Speyer I have recently repeat all the crucial experiments and have come to t following conclusions, which confirm and ampl those previously arrived at.

I find that the serum of a rabbit which has be repeatedly inoculated with mouse cancer fragmen may contain three factors which are toxic to can cells cultured in vitro.

1. A factor naturally present in the sera of ma adult rabbits, which is toxic to any mouse cell. was rather surprised to find that this factor is ve labile and can be destroyed by heating the serum 56° C. for 30 minutes. Addition of fresh rat or mo serum to the heated rabbit serum does not reactiva this toxic element.

2. *Anti-mouse-group Bodies.*—These are not spe fically anti-malignant and very stable; they survi heating to 56° C. for 40 to 60 hours.[1]

3. *Anti-malignant-cell Bodies.*—These are specific the sense that they kill malignant cells and not norm tissues, but they are toxic to many varieties malignant cells and not only to the mouse can cells which were used as an antigen. Such antibod resist heating at 56° C. for four to seven hours.[1]

The first of these three elements is easily demo strated by applying pure serum from an adult norm untreated rabbit to mixed cultures of mouse can and normal tissues. The second by applying t serum of an immunised rabbit after heating t antiserum for eight hours to destroy the first a third groups of toxic factors, fresh rat serum bei added as complement. The presence of the thi factor is less certainly proved since it is more lab than the second and cannot therefore be isolated heating. Antisera made in rabbits are, in my expe ence, less specific than those made in sheep or in ra If, however, great care be taken that the antig injected into the rabbit is pure (i.e., *to wash the mo cancer fragments free from blood and to avoid excess stroma with sedulous care*), I have found that so specificity can be observed—viz., that migrati cancer cells are killed more rapidly than the norm tissue cells. If the antigen is carelessly prepared specificity may be demonstrable. Diluting t anti-serum does not help much since the anti-spec element is still dominant and tends to mask t anti-malignant factor.

The existence of antibodies which have a spec affinity for malignant cells is, however, demonstra in other and surer ways. The clearest proof is suppli by using a particular anti-cancer serum on tiss cultures of cancer cells from a species other than th from which the antigen was taken. Thus if hum breast cancer is injected into a sheep and the shee serum is thereafter applied to mixed cultures mouse cancer, mouse heart, and mouse kidney, or rat sarcoma, rat heart, and rat kidney, every tumo cell is killed in a few minutes, the normal ce survive. Here no anti-mouse or rat element present, unless the sheep's blood originally contain it, and even if so, this naturally existing toxic elem can be eliminated by heating the antiserum for hour and recomplementing with rat complem Conversely if anti-mouse cancer serum from a rabbit applied to tissue cultures of human breast can cells it causes the death of the human cancer ce Again, if anti-Jensen's-rat-sarcoma serum from a she is fully absorbed with rat tissues or even with blood corpuscles and the absorbed serum is th applied to a mixed culture of mouse cancer and mo normal tissues the cancer cells are killed rapidly; t normal tissues are much less, if at all, damaged.

[1] Kohn-Speyer THE LANCET, 1927, ii., 377.

A further proof is that if the serum of a rat hyperimmunised against Jensen's rat sarcoma is applied to cultures of mouse cancer many of the cancer cells are damaged. This can only be as the result of anti-malignant elements in the hyperimmunised rat serum, for an untreated sarcomatous rats' serum never injures cultures of mouse cancer. If a rat instead of a rabbit be selected as the animal in which to make anti-mouse cancer serum a more evident affinity for cancer cells can be demonstrated; presumably the rat being nearly related to the mouse has less tendency to form anti-mouse bodies than the rabbit has.

In vitro results should only be regarded as giving useful indications, and should when possible be confirmed by observations made in the living body. In this instance adequate confirmation of this sort is available, since many rat sarcomata and in one instance a spontaneous rat mammary carcinoma have been got rid of by inoculating anti-human-breast-cancer serum into them—i.e., a serum which contains anti-malignant but no anti-rat elements.

I am, Sir, yours faithfully,

THOMAS LUMSDEN.

THE VITAMIN D VALUE OF COD-LIVER OIL.

To the Editor of THE LANCET.

SIR,—The difficulty in assaying the vitamin D value of cod-liver oil, or of other preparations claiming that vitamin, by any of the methods described by Miss Leigh Clare and Miss Soames in your issue of Jan. 21st (p. 150) is well illustrated by their statement, that after the use of 200 rats only the roughest classification of seven samples of oil could be obtained.
